LIST OF CONTRIBUTORS TO VOLUME CXVII.

Those whose names are marked with an asterisk have contributed editorial articles.

Aaron, Charles D., M. D., Detroit, Mich.
Allport, Frank, M. D., Chicago, Ill.
Anders, James M., M. D., LL. D., Philadelphia, Pa.
Anderson, John F., M. D., New Brunswick, N. J.
Apfel, Harry, M. D., Brooklyn, N. Y.
Aronson, Edward A., M. D., New York.
Aschner, Paul W., M. D., New York.
Ashley, Dexter D., M. D., New York.
*Barr, Gustave, M. D., Vienna, Austria.
Babcock, W. Wayne, M. D., Philadelphia, Pa.
Balderry, Frank C., M. D., Perrysburg, N. Y.
*Bancroft, Frederick, M. D., New York.
Barlow, Nathan, M. D., New Haven, Conn.
Barr, Sir James, C. B. E., D. L., M. D., LL. D., F. R. C. P., F. R. S. E., London, England.
Barsky, Joseph, M. D., New York.
Bass, C. C., M. D., New Orleans, La.
Bastianelli, Raffaele, M. D., Rome, Italy.
Behrend, Moses, M. D., Philadelphia, Pa.
Benedict, William L., M. D., Rochester, N. Y.
Besser, Herman, M. D., New York.
Bishop, Louis Faugeres, A. M., M. D., Sc. D., F. A. C. P., New York.
Blackhall-Morison, Alexander, M. D., F. R. C. P., London, England.
Blaivas, A. J., M. D., Brooklyn, N. Y.
Blau, Arthur I., M. D., New York.
Blauner, Samuel A., M. D., New York.
*Boas, Ernest P., M. D., New York.
Boorstein, Samuel W., M. D., F. A. C. S., New York.
Bosma, H. A., M. D., Groningen, Holland.
Bradford, M. D., E. H., Boston, Mass.
Braunstein, A., M. D., New York.
Brenner, Oscar, M. D., New York.
*Brink, Louise, A. B., New York.
*Brown, Mabel W., A. B., New York.
Buchanan, J. Arthur, M. D., Rochester, Minn.
Cash, S. L., M. D., New York.

Modern Commentaries on Galen

*The Organs of Respiration and the Voice and Their Physiology**

By JONATHAN WRIGHT, M.D.
Pleasantville, N. Y.

The fundamental vice of theory common to every age in the evolution of scientific thought, but most glaringly exhibited in the anatomical conceptions of antiquity, is in making it the master instead of the servant of the mind. In anatomy the ancients formed an idea of what the structure should be to account for or serve for some physiological function badly understood and itself not attentively studied, and then despite the continual obtrusion of anatomical facts upon their attention they ignored them or actually distorted them in the interest of their theories. The internal thoracic anatomy had to conform to the idea that the inspired air, the pneuma, the vital element, the food of life as it still remains, supplied man not with physical energy alone as we now know it, not alone to cool and moisten the blood, as was prominent also in ancient thought and to which we still may not be unwilling to subscribe, but with intellectual and moral faculties as well, the gift of the gods, which were carried with the blood to the heart, thus forming a link of the pantheistic world soul with the human soul. I will not say that in every thinker's mind it was thus so simply and confidently formulated as I have baldly stated it here for the sake of brevity, but essentially this was the trend of ancient cosmic philosophy and of ancient religious thought very much more closely affiliated then than now. It would be a loss of time to show that there had existed ever since Alcmaeon some six hundred or seven hundred years before Christ a better physiological theory than this, but it suffices to say this was the prevailing conception of respiratory function and it is perfectly easy to show how much truth we can extract from it by its liberal interpretation, but from this I must also abstain. The air and the blood in the lungs underwent mutual modifications which prepared them for the heart, the seat of thought and emotion and in fact the centre of life, protected from injury by the soft substance of the lungs around it so that it could not bruise itself as it kicked against the ribs. This was the thought not alone of Æschylus but much later of Aristotle, the greatest scientist of antiquity as Plato was the greatest thinker. The elasticity of the lungs helped it to rebound and added vigor and elasticity to its action. This latter was a conception Plato, in the Timaeus (70 C), furnished to Galen of the heart and lungs, surrounded as they are with strong membranes also protecting them.

Daremberg (1) in a footnote copies a story from Hoffman and Bauhinus, which is sufficiently amusing, as to a dispute two anatomists, who were earnest students of Galen three or four hundred years ago, had with one another while in attendance on a German princeling, as to the position of the heart. In the absence of human dissection Galen had to depend for much of his anatomy on experience with dissection of animals and reasoning from them to man he places the heart too near the centre of the thorax (5), following Aristotle (2), who claims for it this position of honor as the centre of life and thought and, in consonance with the theory above, central, upwards rather than downwards, forward rather than back, though elsewhere (3) he gives its sheer to the left correctly and Galen follows him here again (4). In this confusion of authorities the seventeenth century disputants who had as yet not done much dissection themselves of any kind went astray. The Duke of Baden had palpitation of the heart and his medical counsellor called in two wise men of Heidelberg as consultants. As a result the barber was called in to put a blister over the heart and he put it over the centre of the chest. The prince angrily scolded him for his ignorance and the barber called on the doctor. The latter, being questioned by the irate patient as to the position of the heart, declared it was in the centre of the chest. Still more excited his Highness called for the Heidelbergers. One of them came and said the heart was to the left, whereupon the prince dismissed his attending physician with contumely. The latter rebuked the consultant for his treachery and protested

he had the support of Galen and all the anatomists. The dispute waxing warm and coming to the prince's ears the consultant had to make his assertion good by opening the thorax of a pig and showing the prince the situation of affairs. After a great deal of discussion among the profession whom the bold consultant opposed on the authority of the autopsy while most upheld the teachings of the ancients, a petition was made to the prince and he took back his medical attendant, but at a reduced salary. Even three hundred years after the dissection of the human body had begun we thus see the persistence of the blight of Aristotle's theory. The heart ought to be at the centre of things and if dissection shows it is not, so much the worse for human dissection.

Galen is much impressed by the way the thoracic organs and particularly the heart are protected not only from external blows and jars but from the functional movements of each other. The lungs enfold the heart with five lobes, as fingers would surrounding it in the hollow of the hand, lining the thoracic walls like a veritable air cushion is the idea. He dwells on its tough fibrous structure. Despite the fact he rejects finally and forever the idea the heart is the origin of the nerves, one argument hitherto being based on the idea the membranes around it are nervous in character, he nevertheless feels the atmosphere created by this conception, which Aristotle had adopted from earlier anatomists. The former centre of life had to be protected, as we would say, out of deference to public sentiment, and Galen exhibits this feeling when he partially accepts the view that the heart being surrounded, we may suppose, by so many safeguards is never itself attacked by disease. He modifies this a little by saying hardly ever. Nevertheless the description Galen gives of the anatomy of the heart surpasses anything by far that Aristotle has left or any other author whom we know of before the time of Galen, at least any one of whose work we have even fragments, but for all that from Galen himself, from the fact that he does not vaunt his own knowledge of the vascular system to the skies, as he does his achievements in the matter of the recurrent nerves and the functions of the spinal nerves, from our knowledge of the character of the man we infer he is detailing to us much which was the knowledge of his epoch when he talks of the heart and lungs and the blood current and of the respiration.

In his manual of dissection (*De anatomicis administrationibus,* as Kühn calls it) the themes of which according to our ideas should be entirely objective, undisturbed by any thought except of what can be seen, we find them continually subjected to teleological considerations. The Utility of the Parts, one of his other treatises, with which we are here chiefly concerned, is constantly in his mind. The size of the animal does not determine whether the heart has three cavities or not (the right auricle in Galen's anatomy belongs not to the heart but to the pulmonary vein), it was the air intake and the voice production settled all that. It was a first consideration with him not what he actually saw but what he *should* see to prove that "nature here, as in all other matters, does nothing in vain; everything is of some use" (7). In his striving thus to understand her and to refute Aristotle, he missed after all the significance of the cardiac ventricles and auricles and the way leading to a suggestion of the true mechanism of the circulation, but it is very difficult indeed for the modern student to perceive just what picture he formed in his mind of the course of the blood current in the heart and lungs and the general circulation and one becomes often hopelessly confused with his venoarterial and his arteriovenous terms for vessels and their tunics. The arteries, holding air, had thicker coats to make them air tight; blood being thicker could travel by itself in the veins along thin walled tubes without danger of leakage, and the veins not being stiff they could insinuate themselves better into various localities where they are found. Among the marvels of the providence of God, for Galen found in the ancient religion a basis for his teleology, in the mechanism of the thorax there was a power in the lung itself to contract independent of, yet consentaneous with thoracic contraction. This was the reason the pulmonary artery and veins had soft walls so that they might fill and be emptied by thoracic and pulmonary impulse, but the other veins in which food was prepared it was better to have unchanged so that the blood content was constant. The body is nourished by them, the tissues drawing the blood through their tunics to themselves by their inherent power of attraction. Notwithstanding his frequent revolt from him the entelechy of Aristotle had to interfere with every other thing to get Galen out of a hole.

The pulmonary veins need not supply much nourishment to the lungs as they need but little, hence their wall tunics are denser, but yet not so dense that some of the more attenuated air and such part of the nourishment as was in the form of vapor, sufficient for the scanty nutritional needs of the lungs, might escape through them, not of course the thick and sedimentary part of the blood such as nourished the liver (8).. All we can say in favor of this way of mind working is that the perpetual need for pores through which the contents of the vessels can escape doubtless played its part in all we have learned in regard to the biophysics and biochemistry of the tunics of the vessels in the last two thousand years, and in all fairness to Galen and in the face of all the scientific methods now cherished that must not be forgotten, for after all absolute objectiveness in the workings of the human mind is a mere myth. It is curious to see how close such a method could take Galen, fifteen hundred years before the microscope came into use. "In the whole body there is a mutual anastomosis of minute mouths and openings in both the arteries and the veins and these let pass both blood and air from one to the other through certain invisible and narrow channels."

For the Galenic circulation as well as for the Harveian we see the capillaries, though not found, had to be imagined. These acted it seems not only as communicating channels between artery and vein but the whole as a sort of reservoir for the blood when it surged out of the thorax on expiration causing a compression of the thoracic veins. The channels by which the blood is expelled from the heart are arteries in the modern usage. In the Galenic usage our pulmonary artery was a vein because of its structure and because it was supposed to nourish the lungs. We call the vessels that pour blood into the heart veins, but for the ancients the pulmonary vein was an artery because it carried air from the lungs to the heart, Erasistratus thought without and Galen thought with blood accompanying the air, even though its walls are those of a vein. The heart beat was not due to contraction in our sense, but the impulse felt both in the heart and the systemic arteries was due to the throb of the pneuma. The air that had been taken in and elaborated in the lungs and delivered to the heart or a part of it was the vital force usually identified with the soul of man, thus in direct continuity with the soul of the world.

"The number of the ventricles of the heart is not the same in all animals for in those which inspire the air through the pharynx, through the nose and the mouth, immediately following on these is the lung and the right ventricle of the heart but for the remainder there is neither any lung nor any size to the right side of the heart, for these two things necessarily are intimately dependent on the lungs—the voice of the animal and the right side of the heart" (7). This is not exactly the Latin translation of the Greek text of Kühn nor the French translation of Daremberg, but this rendering seems to me called for despite the disconcerting absence of mention of the larynx. "The right ventricle is made for the sake of the lung, the lung itself is the instrument of respiration and of the voice." To be sure he is only intent on showing that Aristotle was wrong to make the number of cardiac ventricles depend on the size of the animal, yet it is singular that Galen, who elsewhere in this same book elucidates the anatomy of the larynx, in a way he claims originality for in clarion tones, and of which to tell the truth he had a right to be proud in his day, it is singular, I say, that he makes no mention of larynx or trachea or bronchi here where he specifically refers to the voice.

The need of the heart valves is felt and this so obviously they could scarcely escape observation, but the prepossession of the mind with the idea that the chief propulsive power acting on the blood current is the contracting thorax is so great that they and of course their physiological action receive a confused though detailed description (9). A very interesting chapter in the history of the development of our knowledge of the portal circulation is to be found in Galen, but this we must pass over with the remark that though it was allowed in antiquity that the arteries took their start from the heart the veins were said to arise from the liver. Galen even made the pulmonary veins proceed from the heart to the lungs though he knew the blood current was in the other direction, but he has a rather hard time accounting for his inconsistency in the course of which he ridicules Asclepiades (10) and criticizes Erasistratus for saying the structures varied because of the air one carried, that is the aorta, and the blood the other carried, that is the pulmonary veins, though we have just seen him saying much the same thing himself. In fact our knowledge of the very important work of Erasistratus in anatomy is very much confused, even the little we have, by the hostility of Galen, by far the most fertile source of our knowledge of it, due chiefly to the opposition, which Erasistratus headed, with very vulnerable arguments, against the practice of venesection. We know, however, that Erasistratus's idea was that what we call bloodvessels of the lungs are not bloodvessels at all but communicate directly with the air channels and draw from them the air which, thus going to the heart, is distributed through the aorta and the bloodvessels to the general system. The root of the word aorta in Greek we might be disposed to seek for in that of air, but that does not seem possible. Nevertheless it was a word originally applied to bronchial structures and in the oldest Greek writers may be found thus used, Aristotle first identifying it with the vessel which now is its sole application, but it is interesting to know that it came to it from the air channels of the lungs. It is not the place here to try again, as I have in a number of essays endeavored to do elsewhere, to show how attractive and plausible the pneumatic theory, which captivated Aristotle and Erasistratus and many of the other best minds of antiquity, was. Suffice it to say we have largely replaced the pneuma, materialists as we are, with the matter of fact oxygen which is derived from the air through the lungs and goes along everywhere with the blood to refresh and strengthen the bodies of the vast majority of living things.

Incomplete and superficial as is this reference to the physiological and anatomical conceptions of Galen in regard to the thoracic contents, we must now follow him upward in his understanding of the air passages and the specific instrument of the voice. But before we leave the lung one more quotation will reveal the difficulty Galen had with the anatomy of Erasistratus in one respect at least. Galen was sure and could prove it by experiment that the peripheral arteries contained blood but he could not entirely cut loose from the theory of the pneuma, indeed who can, even today? He could not get away from the pressing conviction of antiquity that there was something in arterial blood which did more than give it a redder color. The pneuma must be there and evidently in the lung something did happen to the blood and Galen, no more than Aristotle, could not make out where the air tube left off and the blood tube began. Egyptian anatomy formed a tradition both for Aristotle and for Erasistratus; they were coterminous and there was no blood in the arteries. No more than the Egyptians or Aristotle or Erasistratus did Galen know anything about the diffusion of gases, exosmosis and endosmosis and differentials of absorption, but he denied this for the general circulation. Doubtless they had all seen capillary attraction but knew not the capillaries. They had to go back to Empedocles for the conception of attraction and repulsion and for two thousand years it has clung as a support to his simile of love and hate, as though that explained anything, for who can account for antipathies?

Why, I cannot tell
But I do not love thee, Dr. Fell.

Ah, indeed, and who after all can tell what attraction and repulsion is even outside of the tender passion? But not to wander further from the subject, Galen (11) remarks that behind where the glands project into the cavity of the thorax the windpipe "is there divided and proceeds to all parts of the lung with the vessels which come from the heart, distributed to all its lobes"—this is the Aristotelian anatomy. They must run side by side, that is what makes it so hard to see they are coterminous, is probably the thought of Aristotle, for he goes it blind finally and says: "the trachea is also united with the great vein and with the part called the aorta" (3). Galen insists "it is only in the lungs the tube is entirely free of blood." Occasionally a little vaporous blood is seen in it "but the aspera arteria is entirely free of blood when the animal is normal." It must be confessed with the old Egyptian tradition weighing one down here was a difficulty indeed, the blight of theory.

No doubt it was with a sigh of relief Galen leads away from the subject upwards to our territory; "why is not the windpipe all of it cartilaginous or all membranous by nature, but alternately cartilage and membrane? Why are not the cartilages themselves perfect rings, but each lacks some small portion of it? With this I shall busy myself. First of all it is the function of the cartilage to act as a vocal instrument (12). . . . it is not every stroke of the air is able to produce a vocal sound, but there has to be a certain symmetry and arrangement of the vibrating substance and of its resistance also, whereby the air meets with more or less prolonged opposition, so that it does not collapse, its resistance being overcome." This resistance Galen subsequently explains is furnished by the muscular closure of the glottis. Now when Galen begins to talk about the vibration of the trachea in voice production, we know at once he is on the right track of course but that he is going to miss the significance of the vocal cords when he comes to the larynx. He knows all about the waves of sound from the old Greek nature philosophers, as when you throw a stone into a duck pond, so the ear by the incidence of the air produced the sound. Alcmaeon knew what it was and its effect when it struck like the plectrum of a bell on the hollow bones of the ear, some seven hundred years before Galen was born perhaps. Galen knew something had to vibrate but in going up the air tube from his troubles in the lungs he was a little premature and found the wrong thing doing the chief instead of the lesser "vibrating," and he gets into fresh trouble. "The cartilages in animals," he says, "assume this symmetry in such a way that when less resistant than they are ordinarily, through their laxity, they set the air itself more gently in vibration; when more firm they easily cause it to rebound so that it does not spread out nor resist the impulse received, but is cast upward and flows out in a manner similar to a current rather than to a gust and thus exhibits the effect of its energy." There is nothing very wrong about this except he has set the wrong structure to do all the vibrating.

Much more correctly even than is found ordinarily in modern textbooks as to its function he nevertheless overstresses the part the trachea plays in voice production, its lengthening and shortening, its dilatation and contraction. We have also been led astray by the interest the complicated laryngeal mechanism has aroused in our minds to neglect the part played in voice production by the tube below the rima glottidis. The cartilages of the tube, resonant, flexible, elastic, engaged the attention of Galen more than intra and extra laryngeal muscles and ligaments in voice production. "Its cartilages are the instruments of the voice itself, the bands that bind them together those of respiration. Moreover, that it is the cartilage is the prime instrument of the voice, the larynx is especially a document of proof to thee; that I have already shown in my book on the voice (which is lost) is the chief as it is the first one and that it is unnecessary that it should be all one cartilage is apparent to any one." . . . The trachea first assembles the sound and prepares it for the larynx and the palate like a kind of gong or reverberator resists the voice and the uvula, like a clapper, swells it.[1] "Not simply in expiration is the voice formed, but yet the blowing of the air is the real substance of the voice and in its way of working it differs from expiration in breathing although the muscles of the thorax cause that too. That has its own method of action and so especially does the voice." He again speaks of the trachea and declares it is the immovable state of its cartilages has to do with voice production and it is their motion has to do with respiration. In Cicero we get the idea that the teeth took the place of chords in string instruments producing sound, in ancient thought (16).

This resonance idea we see prominent in the way he treats of hoarseness—destroy the cartilage and it supervenes at once, despite the soft parts are left intact. He does not primarily say, cut the ligaments or muscles and the voice is lost. It is a framework matter chiefly for him. It is the differentiation in the relative prominence of parts of the ancient thought as contrasted with those of the modern to which I wish to draw your attention and then I want to show how much that depends on the ideas which run underground through the minds of men who have no or only the remotest connection with medical thought in general. We are always failing to realize how much we depend on humanity in the mass for our opinions and we are continually laying the flattering unction to our souls that we direct and do not follow popular currents. Galen no more misses the moving and moveable laryngeal parts than we entirely neglect the resonant parts of the organ of voice which lie below the rima glottidis. When an outsider, when Garcia showed us the workings of the vocal cords we fell into line with a sentiment, which overshot the mark.

But in the days of the ancients the importance given to the length of the trachea pervaded the lay mind and we find it formulated in the resonant lines of their poets. The swan sang its death notes and imagination made them sweet, imagination pure and simple as any one can testify who has ever heard a swan squawk. Such an one will ever remain unconvinced their notes are melodious in the article of death. For Homer the cranes, which flee from the coming winter and sudden rain, fly with clamor towards the streams of ocean (*Iliad* III.5). The magnificent lines of Virgil (17) have been translated by Glover with scarcely less splendor:

> Like snow white swans in liquid air,
> When homeward from their food they fare
> And far and wide melodious notes
> Come rippling from their slender throats
> While the broad stream and Asia's fen
> Reverberate to the sound again.

---

[1] I make my own interpretation of this part of the Greek text as that of neither Kühn nor Daremberg is here very satisfactory, but I imagine it is the thought as well as the language of Galen is here obfuscated.

Now all this was because swans and cranes had long tracheae and Galen, referring to Hippocrates's description of the voice in certain morbidly dry states as clangorous, repeats the line in Homer I have quoted and says: "thus it is in all animals who have long necks and dry cartilages, of which kind are the cranes." I do not know what his opinion was of the singing notes of the giraffe, which Cæsar first showed at Rome in his triumphal games.

I should perform a tiresome service were I to point out how much less of the ligaments and nerves and muscles of the larynx Galen knew than we do and I am poorly adapted to such anatomical criticism, owing to my far flung and deep extending ignorance of modern anatomy, and I flatter myself I am performing better service and a more interesting one in thus laying emphasis upon some of the causes of the variations of much in the Galenic physiology and anatomy from our own. This I take it is a part of that psychology in the history of thought which it is absolutely necessary for the future historian of science to lay bare before us. It can only be a trifle in a special field such as ours but it will serve in illustration and it is neither useless for us to mark it nor is it entirely devoid of casual interest to go beyond the special field in trace of it, though the teleological bias is there also sufficiently obstrusive. The tracheal tube is not only long and therefore must be superior in sound production, but the tracheal cartilages are hard, oval and arched in front to act as bulwarks to external violence and spanned behind by soft resilient contractile bands to allow deglutition to take place without disturbing the essential parts of the vocal function of the trachea, which for Galen bulks so large in voice production, so all wise, so skilful is the Creator of all things, for we must not forget that Galen, like most successful practitioners, was a pious man. How else could God have made it better? Did Epicurus and Asclepiades think they could have made a better job of it? This great book of Galen on the Utility of the Parts he declares is largely written to demonstrate the wisdom and glory of God, and with this statement we get another line on the psychology and the mentality and the methods of thought of the author.

The anatomy of the larynx as set forth in the works of Galen doubtless represents an advance over that of his predecessors. When we come to that part (13) of it dealing with the cricoarytenoid and cricothyroid articulations the translation of Daremberg departs so widely from the text and translation of Kühn that we must surmise a fuller text was at the service of the former than Kühn used. Even the latter does some violence to the text he furnishes, which results in a stretching of the knowledge of Galen at this point. The text as I read it says the two cartilages, the thyroid and the cricoid quite evidently, articulate with one another aslant or obliquely, but Kühn translates it (*dearticulantur autem et committuntur inter se partibus obliquis*) "with oblique parts," which may mean oblique surfaces or oblique fibres of the cricothyroid muscle, but does not surely mean one or the other as it stands in the text. Daremberg; however, says, "they articulate one with the other upon the side by an arthroidea by means of the small horn of the thyroid and the articular apophysis of the cricoid." (*Ils s'articulent l'un et l'autre sur le coté par arthrodie au moyen de*—etc., etc.) Now I am not a paleographer and I would not enter into this discrepancy were it not that it seems as though, if Galen had in his mind as sharply defined as the translation of Daremberg indicates the anatomical relationship of the parts, he would be on the track to a knowledge of the physiology of the vocal cords as we understand them and even the latitude of Kühn's rendering suggests the same. It is true the text here is not very satisfactory for as it goes on to the arytenoid joint it defines the articular surface as convex at the point "where the cricoid leaves off." Daremberg intercalates certain words in brackets which do not exist in Kühn's Greek text of Galen but which are to be supposed to represent Daremberg's conception of the meaning of the passage, and so far as the warrant of the Kühn edition goes he transgresses still more seriously by not including still other of his own ideas in brackets. The result is, when the reader compares the two translations, the Latin of Kühn and the French of Daremberg, with one another and then compares them each with Kühn's Greek text, confusion reigns.

As I have said, I am no paleographer and I am not much of an anatomist, but I cannot but help wishing some one combining the two qualifications would treat the various texts of Galen at this point, if at no other, as the importance of it in the history of laryngeal anatomy demands. Then Kühn's text and translation passes on to speak of the cricoarytenoid joint. On the cricoid "there lie two small convexities." Here therefore begins the third cartilage (the arytenoid, Galen's number for the laryngeal cartilages was three, the arytenoid being a single cartilage with two articular surfaces at its base) having cavities exactly fitting the latter eminences so that the meeting of these two cartilages (the cricoid and the united arytenoids) make a double joint. Now this mistaken conception of Galen himself is perfectly clear and with those surfaces before his eyes or in his mind, with the arytenoids forming a single cartilage, there should have been for him no sliding joint and no swinging joint either, as Daremberg interprets him. No lateral folds of the mucous membrane even, if he made out the tendinous structures within them, could have had any significance for him. His book on the voice has been lost and we do not know how far in that he went in the anatomical and physiological description of the parts, but we have every reason to infer, with this fundamental error of observation, he could not have grasped the nature of intralaryngeal movements, yet he says, evidently referring to the lost treatise: "How first the voice may be formed in the larynx, how the latter is most dilated and compressed, opened and closed exactly above its orifice is shown in other writings." Kühn's translation is not very happy here either, but the necessary emendations, which a laryngologist can supply, are not great and do no violence to the text. Galen's conception of opening and closing the larynx is essentially a purse-string mechanism (14), and this seems all the more remarkable because his knowledge of the internal and external musculature and the membranous and tendinous structure was surprisingly extensive if not very accurate, but I have no intention of going into details. It is moved by twelve muscles proper to its structure, my notes on this part of his discourse say, so far as it has relation with neighboring parts by eight others. In animals with a loud voice he seems to think the arrangement if not the number differ a little, but after all he cannot get away from the pneuma. That the animal should produce a voice, the air must be set in motion with something more than a simple expiratory sigh, but at the same time the glottis must be made narrower and wider in the passage of the air through the larynx and in this act the muscles of the chest in the first instance and those of the larynx in the second place must be brought into play. However, I must leave Galen's struggles with the mechanism pure and simple of the larynx and pass to his great claim to our respect—his demonstration of the recurrent nerves.

The 14th chapter of the Seventh Book of the Utility of the Parts marks a great epoch in the history of our knowledge of laryngeal physiology (15), and one is infinitely amused to see how well Galen knew it and how his vanity swelled, burst and ran over into loud jubilations of self laudation. It is long drawn out and I cannot translate it all. It was too sweet a morsel for Galen to abbreviate and we must perform that painful task for him here: "Everyone will marvel if he will but lend his mind to what I have to say here . . . You must show yourselves more attentive than if you were taking your initiation at the Eleusinan or Samothracian mysteries or at any other great solemn ceremony of the kind, so great because of those things which are done and said by the priests. You will stand in wonder and think this is nothing inferior to those sacred things nor less indicative of the power, wisdom, foresight, and goodness of the Creator. Listen then to me, for I am the first of all to discover these sacred things. No one before me has perceived any of these nerves nor any of these things which I have found in the larynx as before described, their cause and their action. The anatomists have all erred and they have not touched upon a tenth part of them. Turn, therefore, if thou hast been lax before, and now at least be an attentive and worthy listener to what is about to be disclosed; follow my discourse setting forth the marvelous mysteries of nature."

The nerves in the time of Galen were not yet fully differentiated from the membranous and tendinous structures which on superficial examination they resemble. It is not altogether clear how much he had to do with this movement which probably was well under way when he began his studies. We find him seriously imbued still with the idea they have some mechanical action like a string on the muscles in which they end, an affinity still and sometimes a confusion with the tendinous parts of muscles at their insertion. As the recurrents curve around the great vessels this notion especially took possession of him as though thereby on the principle of the pulley they have a drag downward. Their oblique course, he thinks, saves them from the strain of the direct pull. In this connection he reminds the reader, nevertheless, of their origin in the brain or its prologation and that they do not come primarily from the heart, the center of all things Aristotelian. All muscles receive the nerve in their heads or near it, at least above the middle of the body. If in the center, as of the diaphragm, all fibres draw towards the centre. "This is common to all muscles and divisions (of the nerve), extend to that part towards which their fibres converge. If you keep this in mind you will be convinced, I think, why it is necessary for the nerves to be inserted in the laryngeal muscles from beneath. It will also be understood why the muscles that close and those that open the larynx need not be of the same size. The openers (postici) do not have to oppose the expulsory force of the thoracic muscles, considering which in their physiological rôle of voice producers he has considerable discourse, and because of the force necessary for the muscles closing the larynx it needs must be that the nerves should enter them in a straight line with their heads, since by means of the muscles the arytenoid cartilage is dragged upon" . . . If the nerves came from the heart, "as some think, ignorant of all things which concern dissection," this would be provided for by another arrangement, but coming from the head or spinal cord as all nerves do, they would enter from above downwards and obliquely, except that an all wise Creator took them into the chest and wound them around the vessels like pulleys, being as they are "branches of the sixth nerve," as he called the pneumogastric. "From the posterior part of the brain the derivation descends straight through the whole neck on each side of the aspera arteria, alongside of which there lie certain other small parts joined to it." There is no textual reason why he was not familiar with the relations of the sympathetic and the spinal accessory root, but it is not very easy to be sure we are not imputing more to his objective anatomical knowledge than we have warrant for. However, from this superficial and imperfect sketch, incomplete as it is and exhibiting only partially the enormous discrepancy between his knowledge and ours, in spite of our suspicion that much of his knowledge is derived from his predecessors and his contemporaries, we must recognize in Galen the first great expositor, if not the greatest expositor, of the anatomy and physiology of the organs of respiration and the voice, who has ever lived, at least of whom we have any knowledge.

The Establishment of a Temporary or Permanent Pulmonary Lip Fistula in the Conservative Treatment of Advanced Bronchiectatic Lung Abscess*

By WILLY MEYER, M.D.,
New York City,
Attending Surgeon, Lenox Hill Hospital.

(Reprinted by courtesy of the Editor of the New York State Journal of Medicine.)

When the late much lamented chairman of your section, Dr. Henry L. Lynah, the consulting peroral endoscopist of our hospital, the Lenox Hill, of New York City, invited me to take the surgical part in the symposium on pulmonary abscess, which he had arranged for this meeting, I accepted without hesitation, as the subject is of particular interest to me.

After some deliberation as to what phase of the topic assigned to me I should bring out, I came to the conclusion to briefly discuss the Conservative Surgical Treatment of Bronchiectatic Lung Abscess.

Personally I feel inclined, from a mere clinical point of view, and aside from exceptional cases as actinomycosis, suppurating hydatid, and others, to divide nonspecific or subacute chronic lung suppuration into three classes:

1. The ordinary lung abscess, subsequent usually to pneumonia or influenza; 2, the typical bronchiectasis, viz., multilocular lung suppuration, due mostly to congenital origin; 3, the bronchiectatic lung abscess, consecutive to the aspiration of septic, semisolid, or liquid material, or also due to embolism of small size and a low degree of infection, both producing local gangrene. Each of these three classes requires different treatment.

Without going into the merits of the various more or less conservative procedures proposed for the treatment of lung suppuration, I would today present the result of personal endeavors made to relieve the bronchiectatic lung abscess, by incising the principal cavity of the lung, a procedure which naturally includes the attempt to reach a larger bronchus or its branches, for prolonged drainage, the latter to extend over many months or even years.

In some of these cases one larger, irregular cavity is present, or two (or more), sometimes smaller ones, communicating with each other and with that branch of the main bronchus, through which aspiration took place, and which is drained outwardly when the cavity is successfully reached and opened.

The endeavors just referred to resulted in the working out of a method which, it seems, often cures the active lung disease in a very simple manner, viz., by thorough, direct and prolonged drainage, and increased ventilation, secured by means of establishment of a temporary or permanent lung-lip fistula.

Before describing the method, I should like to give here a brief history of the events that led up to its adoption.

In the years 1908 to 1912, while doing experimental work on dogs at the Rockefeller Institute, we found that healthy dogs stood the removal of one or more lobes of the lung nicely, if operated upon under differential pressure and, of course, under strict aseptic precautions. They were almost well after forty-eight hours, jumping around and barking, as if nothing had happened. On testing the contents of the chest in the place of the removed lung lobe or lobes with an aspirator, we found air, never fluid, in contrast to the experience of Robinson and Sauerbruch, who always found fluid (1). I believe, with a perfectly aseptic course of healing after lobectomy in the healthy dog, with separate ligation of the bloodvessels that accompany the bronchus, and crushing combined with airtight inversion and suture of the bronchial stump, also complete closure of the chest, air will be found as a rule within the chest in place of the excised lung portion, and not serous fluid (2).

Of twenty-six dogs thus operated upon, twenty-two recovered or 84.6 per cent. (3).

Subsequent observations of the effects of lobectomy in dogs showed that Nature tries to eliminate the defect, created within the chest, by a gradual distention of the remaining lobe on the side operated upon, as well as of the entire lung of the other side (compensating emphysema), correspondingly changing the position of the mediastinum, diaphragm and chestwall itself. Whenever the entire lung has been removed, the opposite side crowded over, but the tissues did not become adherent to the other costal pleura; they formed a kind of new pleural cavity.

Anatomical proof of this work of Nature was made possible through the courtesy of Dr. Francis Carter Wood, of New York, who was good enough to give his valuable aid in these investigations. He bled to death the dogs treated with lobectomy, at various times after the operation under general anesthesia, through an incision in the femoral artery, then using this opening to inject a five per cent. formalin solution into the vascular system. After thorough hardening and freezing of the entire animal, transverse section cuts were made through the chest at various levels. The specimens thus obtained were very instructive. Some of them were shown before the American Surgical Association at its Washington meeting in 1910 (4). They are still in my possession.

Enthused by this favorable experience in dogs, we approached our first lobectomy in the human being with great hopes, on May 12, 1909. The case, a boy of six years, had shown the clinical signs of what seemed to be a bilateral bronchiectasis, concerning both lower lobes, of more than two years' duration. He had come under my care through the courtesy of the late Dr. Pisek, of the Post-Graduate

Hospital. With the patient's head and the anesthetiser under positive pressure, within the cabinet—the only apparatus for differential pressure then available in science and at the Lenox Hill Hospital, outside of the negative chamber, which had not yet been installed—we loosened the adherent lobe and treated the pedicle, bronchus, and bloodvessels as we had learned to do it in our experimental work. Today we know that such detailed treatment of the stump is not advisable in human beings. After the vessels were doubly ligated and divided we crushed the bronchus with a powerful clamp and, just as we were inverting it, after tying, the anesthetiser informed us that the patient's pulse had suddenly become weak and respiration very superficial. Soon the heart stopped beating; persistent attempts at resuscitation failed. We all were utterly disappointed and unhappy, and tried to explain our experience in various ways: Acute dilatation of the right heart on account of the continuous increased air pressure, in the face of a heart muscle, weak and diseased from years of septic infection, vagus reflex, and so forth.

The experience just related occurred a few weeks before the arrival of Dr. P. Friedrich, then professor of surgery at the University of Marburg, Germany, who had come to America in the spring of 1909, at the invitation of the American Medical and the American Surgical Association, to attend their annual meeting. On discussing the boy's death with him he gave me the following advice: "Do not attempt to excise every chronically suppurating bronchiectatic lung lobe in the human. Lobectomy is still a very serious operation, and thoracic surgery is still a very young child. The many deaths that would most likely result, might give thoracic surgery a black eye in the estimation of our medical brethren. Rather go ahead slowly and cautiously and try conservative methods first."

I took his advice and, in the course of the subsequent years, conscientiously and faithfully tried every conservative procedure known in the surgical treatment of bronchiectasis: artificial pneumothorax, collapse of the chest wall by the socalled extrapleural thoracoplasty (multiple rib resection), ligation of a branch of the pulmonary artery with and without subsequent thoracoplasty; incision of the lung with drainage, and, resection of the lung, lastly, bronchoscopic treatment at the hands of experts.[1]

One of the results of my attempts to help some of these seriously afflicted patients in a more conservative way was, as mentioned above, the working out of a method which promises satisfactory results in a more roundabout fashion in patients suffering from the socalled bronchiectatic lung abscess, though it will naturally not cure the patient as completely as the excision of the diseased portion or portions of the lung. It consists, in brief, in the establishment of a pulmonary lip fistula, which, after the principal cavity is emptied of its contents: pus, old fibrinous coagulations, and grumous material, ventilates the same directly; and this, interesting to observe and to state, does away definitely with that terrifically foul odor of the sputum. As I have frequently stated when presenting such patients before medical meetings, it is evident that the free access of a larger volume of oxygen to the evidently partially anaerobic microbes, which settle down in these cavities and are, I believe, responsible for the terrible odor, destroys them permanently. Repeatedly I have succeeded in hastening this happy change by making the patient close his mouth and compress the nose, thus forcing respiration through the artificial opening, often also having the nurse blow a stream of pure oxygen gas into the fistula several times daily, with inspiration through the same on the part of the patient. The sputum, too, ceases after a while.

When the patients have recovered and been discharged from the hospital, they appear perfectly well. In case of a severe cold, or of undue, and, of course, forbidden, exercise (bicycle riding, dancing, playing tennis, or other violent exertion) temporary exacerbation may set in later on with accompanying cough and reappearance of sputum which is often streaked with blood, and mild fever. However, these phenomena are only temporary; the patients soon regain their former greatly improved state; they are able to work, their weight increases; bachelors even get married, and usually they are so well satisfied with the improvement attained that they refuse the second part of the work planned: the closure of the canal or opening. So far I have had no chance to attempt closure of the lung fistula, which, I think, would best be done by means of a circular excision of the skin lip fistula, cauterization of the canal that leads into the lung and collapse of the chest wall by means of extrapleural thoracoplasty. In two of my patients this lip fistula has closed spontaneously; both are completely cured.

Of course it must not be forgotten that so long as the canal remains open these patients cannot be considered cured in the true sense of the word. They cannot take a bath, even in the tub, or go in swimming, nor must they ever fall into the water, for instance, while out fishing. Instantaneous death by flooding the lung would be the consequence.

It is true it might be possible to close the opening with a cork and in addition construct a snugly fitting, safe suction rubber cap, with inflatable neck, as we see it attached to the masks for general anesthesia, to make the fistula airtight. Still, with their body immersed in water, their life would depend on the proper working of such a device. The slightest leak, and they would drown instantly.

There can be no question that extirpation of the affected lobe or lobes is the best and the most radical surgical treatment. If the patient pulls through the operation, he is completely cured of his terrible affliction. In the pronounced type of congenital bronchiectasis, also in advanced acquired multilocular cavity formation of the lung, resection is the only operation that comes into consideration.

On the other hand I am convinced that there are many weak and reduced patients with acquired and advanced chronic nonspecific lung suppuration, particularly the bronchiectatic pulmonary abscess, in whom radical work is absolutely contraindicated, who would succumb to the extirpation of the diseased portion of the lung. In other cases the radical operation is refused by the patient or his relatives.

In such instances it is important to know that a less severe operation can bring some of these patients back to a very satisfactory state of health, even to complete cure and restore them to useful membership in the community.

---

[1] I did not try the subdiaphragmatic transposition of the affected lower lung lobe, in combination with and rendered possible by artificial paralysis of the diaphragm on the same side, by means of phrenicotomy, as proposed by Henschen, as not much is known about this procedure so far.

In conclusion, I would again emphasize that we are just entering upon this new and last chapter of operative surgery, viz., thoracic surgery—that we are still groping our way in trying to establish indications as to which one of the various useful operations should best be selected for the case in hand.

One word to our friends, the radiographists. It is true they have already done a great deal in assisting the surgeon in locating the principal focus within the large thoracic cavity. Once Dr. William H. Stewart, the radiologist of our hospital, stated in his report: "Measure eight inches down from the spinous process of the seventh cervical vertebra and from there two and a half inches to the right. If you plunge your aspirating needle at this place, you will find the abscess." I followed his instructions and struck the pus. But this remained an isolated, exceptionally fortunate occurrence.

The radiographists should develop their branch of our science still further. They ought to furnish the surgeon with still more explicit data than their fascinating stereoscopes reveal. We need more detailed information, so essential for operations on conservative lines, regarding the actual distance of the principal focus from the front as well as the back and sides of the chest; we ought to be able to guide our aspirating needle by their advice, in which intercostal space we should enter, whether we should push the needle forward in a straight sagittal line, or in an oblique direction and so forth.

But our principal efforts should turn in the direction of avoiding the development of this dreadful disease—in the direction of prophylaxis. We know that aspiration of foreign substances, solid, semisolid, and liquid, represents the most frequent cause for the development of this trouble. Let the physician remember that the sudden onset of an unusual cough points to such aspiration, and demands the immediate calling in of a trained bronchoscopist for consultation, besides taking an x ray picture of the chest; let the specialist arrange his tonsillectomies and adenoidectomies in such a manner that aspiration of blood, mucous and septic material can not and will not occur; and let the surgeon bear in mind, should he be called into such a case early, a number of days after an operation, when the incessant cough with foul expectoration and high fever has just begun, I say, let the surgeon bear in mind that surgical interference of any kind inclusive of the establishment of an artificial pneumothorax, is not indicated as the first step, but that a trained bronchoscopist is also his best friend.

In the spring of last year such a patient came under my care. Fourteen days before, her tonsils had been removed under general anesthesia, at another hospital, up to which time she had been perfectly well. She now suffered from a most distressing cough, day and night, neither medicine nor therapeutic procedure of any type bringing the slightest relief, with a terribly foul and massive sputum and fever up to 104°, the typical picture of a socalled aspiration pneumonia with incipient lung suppuration. Having previously often discussed this very picture in its first development with our departed friend, Dr. Lynah, holding that this would be the time for bronchoscopy and thorough aspiration, irrespective of fever and the patient's general condition, I called him in consultation. He promptly did his wonderfully dextrous endoscopic work, and after a few days cough and sputum had ceased as by magic and the fever had dropped. The patient was the happiest woman in the world, and we were all equally delighted. I begged her to stay in the private hospital at least one week longer for observation, and, if necessary, have Dr. Lynah repeat bronchoscopy with aspiration. But she left, considering herself perfectly well. I then lost sight of the patient and was unable to locate her, in spite of careful search, until, a few days ago, through our faithful social service nurse, the patient was found. She was entirely well, had no cough, no sputum, and expressed her gratitude for the splendid treatment she had received at the hands of Dr. Lynah.

Some Principles of Immunology Applied to Treatment by Artificial Pneumothorax*

By NATHAN BARLOW, M.D.,
New Haven, Conn.,
Surgeon (Reserve), United States Public Health Service.

The results of artificial pneumothorax in properly selected cases are usually gratifying, and in some cases almost miraculous, considered with reference to the period of time immediately following the treatment. Let us consider the reports of ultimate results by experienced men who have followed their cases over long periods of time, and whose papers bear evidence that all patients who have dropped the treatment for any reason (those who have developed complications which eliminated them, those who fell into special classes for any reason and all classes of irregular cases) have been included in their series. Of those in your own immediate vicinity, Minor (1) reports twelve and a half per cent. of permanent recoveries, Ringer (2) reports thirteen per cent. permanent recoveries, and in the literature, generally, but few report more than twenty per cent.

of cases in which long continued arrestment has been attained. These reports are by men of seasoned judgment, who are able to justly apportion the credit which is to be given the treatment, and who have recovered from the first enthusiasm aroused by a new treatment.

A general review of the literature makes it evident that the victims of tuberculosis have on the whole been benefited by the introduction of artificial pneumothorax, but the permanent benefit received is disappearing for a treatment which, when first applied, produces so marked and prompt a change in the condition of the patient. In this paper I will endeavor to show that much better ultimate success could be attained if it were not for the failure of the physicians using this treatment to recognize certain principles which should be applied in the care of the patients. These principles are partly immunological and partly mechanical, the first group being the most important.

Of the biochemical processes taking part in the resistance of the body to tuberculosis, the following three will be considered. Each of these is a group of reactions, and not a single process:

1. Local resistance to invasion. This includes both the power of the cells of a particular region (the tubercle and its vicinity) to withstand or destroy poisonous products of either the bacilli or the tuberculous tissue, and the allergic tissue response which causes the hyperplastic wall of defense to be built up.

2. General antitoxic immunity: This includes the reactions by which the body destroys, neutralizes, eliminates and withstands the poisonous products which are produced by the bacilli and by the tuberculous tissue, and which reach the general circulation. It should be remembered that a toxic substance is not necessarily a toxin proper, and that the expression antitoxic immunity makes no assumption as to the nature of these toxic products. The antitoxic immunity is measured by the amount of these toxic products which the body can endure without constitutional symptoms, apparent injury to the tissues, or apparent interference with function.

3. Metabolic processes: All the reactions of resistance are metabolic in their nature, and require expenditure of energy on the part of the cells of the body which take part in them. Demands are therefore made upon the nutritional and eliminative functions in excess of the basal requirements of the body. In these, as in all metabolic processes, there are required certain special substances, some of which are elaborated in the endocrine glands and some probably elsewhere, the supply of which is not unlimited. These unusual demands do not cease when resistance is established, as the replacement, elimination, and repair of diseased and necrotic masses of tissue continue to tax the reparative power of the body.

The local resistance to invasion is by no means equal in different parts of the same animal body. Wassermann and Citron (3) have shown for typhoid bacilli that the bactericidal immunity is greater in the location in which the immunizing injection was made. Roemer (4) has shown the same with reference to the antitoxic immunity against abrin. Von Pirquet (5) has shown that the allergic skin reaction is greater in a region frequently used. We are all of us familiar with extensive tuberculous lesions which for long periods seem to progress only in certain areas, usually those last invaded. By analogy with every immune process with which we are familiar, we are driven to the conclusion that the tissues in the immediate vicinity of the most recent lesions, and which have been subjected for the shortest time to the action of concentrated toxic products, must, within certain limits, have the least welldeveloped resistance.

In the artificial production of immune reactions of every sort, we must begin with small doses of the antigen (toxin, bacillus, protein, or whatever substance we are using). With gradually increasing and properly spaced doses, the degree of the immunity is gradually raised, but if doses which are too frequent or too large in proportion to those against which immunity has been established are used the resistance is overwhelmed, and the result is injury to the animal, and decrease instead of increase in the immunity. There is every reason to believe that the local resistance against tuberculosis follows the same laws, and that it may be diminished or destroyed in the region of a very active tubercle, and yet be efficient in the neighborhood of older and less progressive lesions. In practice with patients who are not receiving pneumothorax, we base our treatment, not upon what we find in the oldest and most advanced lesions, but upon the turn of events in the most recent extensions. Why then should we assume that as soon as we have induced pneumothorax, all of these laws are reversed, that progress in one part can not take place unless the disease is everywhere progressive, that the local resistance in the collapsed lung is immediately raised to a perfect degree, that advanced caseous lesions can heal and cicatrize in a few weeks, and even that signs of pathological activity in the uncompressed lung can be disregarded, signs which would cause us grave concern if we discovered them in one of our other cases. I have seen patients who had been discharged from sanatoria with both physical and x ray evidence of advancing disease in the uncompressed lung, although with almost no clinical symptoms; apparently in this same blind faith that artificial pneumothorax alters or even reverses all of the clinical, immunological, and pathological laws that govern the course of tuberculosis.

The general antitoxic immunity and the local resistance to invasion are ordinarily more or less proportioned to each other. In clinical terms, the symptoms usually correspond in a general way to the rate of extension of the disease. But we are all of us familiar with cases in which this correspondence does not hold good. We frequently see wellnourished, afebrile patients in whom the disease is steadily progressing; although we know that sooner or later, if the disease is unchecked, the constitutional immunity to the poisons of the disease will break down, and the condition of the patient become similar to that of the usual far advanced case. All of us who have used tuberculin in treatment know that tolerance to relatively large doses is readily attained, even though the disease may be unchecked in its course. Dr. Dorset (6), of the Bureau of Animal Industry, has found that tuberculin tolerance may be established in cattle without interfering with the ophthalmo reaction, and that when slaughtered, these cattle show no evidence that the tuberculous process was in any way altered by the antitoxic immunity against tuberculin. DeFosset (7) reports that cattle may be apparently healthy and tolerant of tuberculin, and yet respond to the ophthalmic tuberculin test and show well marked lesions of disease when slaughtered. It is clear that the general tolerance is similar to the desensitizing immunity established against anaphylaxis by any foreign proteid, when proper doses are administered. It is a reaction to which many tissues contribute, its development will therefore be proportional, up to a certain point, to the amount of these poisons (antigens) which reach the general circulation. On the other hand, the tissues immediately adjacent to the tubercle have for a long time been receiving more than the optimum stimulus, and the fact that the disease is progressive shows that they are incapable of responding sufficiently to meet the requirements.

The degree of antitoxic immunity (tolerance) is determined by the dosage of toxic products (antigens). If this daily dose is large, and the body can take care of most of it, so that there are but moderate symptoms, we must expect that any marked reduction in the amount reaching the circulation will be signalized by a disappearance of the clinical symptoms which are due to those poisons. We see this illustrated in the far advanced patients who have been ambulant before entrance into the hospital, and have therefore been inoculating themselves with enormous doses of these tuberculous products. After being placed at rest, they not infrequently have an afebrile temperature as long as they remain in bed, even though their disease is advancing more or less rapidly. Of course the least exercise causes an elevation of temperature, but under the conditions of complete rest, their general antitoxic immunity is adequate to prevent fever, although their local resistance to invasion at the sites of the lesions may be almost nil.

A much greater reduction in the amount of toxic substances reaching the general circulation is brought about by artificial pneumothorax. During the period immediately following its production the collapse of the lung presses out a certain amount of lymph which bears toxic products, and during this period the temperature is often increased. This gradually becomes less, the rate depending upon the manner of treatment as well as upon the pathological condition present, until finally the complete rest of the diseased lung reduces the amount of toxic material reaching the general circulation to a fraction of that which previously escaped from the lesions. This is followed by a return of the temperature to normal, and by a disappearance of most of the symptoms usually regarded as evidence of toxemia. But this reduction of clinical symptoms is due to the reduction of the amount of toxic substance in the circulating blood in a patient with an antitoxic immunity of the degree produced by the previously very much larger dose. It is not due to healing of the lesions themselves, and bears no relationship to the local resistance of the tissues surrounding the lesions. It is true that the tubercles are now in a position more favorable to healing because they are situated in a tissue which is at rest, but there will be the same conflict between the forces of repair and the forces of destruction, as there is in any tubercle situated in some other organ than the lungs. Artificial pneumothorax is usually performed in advanced cases with numerous large tubercles and caseous foci, and often with chronic fibrocaseous lesions in which the tendency to rapid healing is reduced. Such lesions in any part of the body would require months of the most rigid treatment, followed by months or years of careful supervision to effect a cure. And yet after the performance of artificial pneumothorax, such patients are sent to their homes after a few weeks of treatment, allowed to resume their occupations, and the only injunction laid upon them is that they return regularly for their infection. Artificial pneumothorax does not alter the laws of nature, nor does it take one jot or tittle from the necessary steps in checking the progress or in the repair of pathological processes.

The antitoxic immunity is of course subject to a gradual reduction in degree following the reduction in the amount of circulating antigen. There are no accurate observations as to the rate of loss of tuberculin tolerance, but experience derived from tuberculin treatment shows that it is safe to begin with a reduction of twenty-five per cent. after eight or ten weeks of cessation of treatment, and with a fifty per cent. reduction after many months. Krause (8) reports the persistence of congenital sensitiveness in a guineapig after 404 days. As the amount of toxic substance in the circulating blood after a complete collapse must be a small fraction of that present before, it is clear that there must be a very marked increase in the disease before this amount will again rise above the threshold of the quantity necessary to produce clinical symptoms. The clinical guides to treatment are therefore entirely misleading after the induction of artificial pneumothorax. We can not expect clinical evidence of activity until extension of the disease has reached a dangerous or even hopeless degree. We should therefore treat patients under artificial pneumothorax with reference to the pathological condition, and not according to the indications which the clinical symptoms would afford us in uncompressed cases. We should consider even the slightest clincial symptoms as of grave import, and should remember that we may have extensions with almost no symptoms. This does not mean that we should treat such cases with the same régime and for the same length of time that it would take to heal the same pulmonary lesion if uncompressed. A better rule would be as follows: Give every patient under artificial pneumothorax a course of treatment which would probably result in the arrestment of a surgical tuberculous lesion equal in extent to the compressed lesion, with pulmonary involvement equal in extent to the lesions in the uncompressed lung, plus the ineffectually compressed lesions which there may be in the treated lung. Pay no attention to absence of fever or gain in weight or strength, but give the same preliminary complete rest, and the same gradual increase of exercise that you probably would in the hypothetical case, which would of course show clinical symptoms at a much later date than does the real case.

The demand made upon the metabolic processes requires special consideration for several reasons. The patient has been for some time suffering from the toxemia of advanced tuberculosis, with the consequent degeneration and weakening of the heart, digestive, secretory, and other organs, and is scarcely able to meet the metabolic requirements of normal life, entirely apart from the requirements of repair. This degeneration and weakness is not recovered from in a few weeks or even months, and it would be poor practice to allow a patient with an equal grade of debility and neurasthenia to return to any occupation until after full recovery, even with no tuberculosis. By contrast with their former condition, these patients feel that they are well, and are likely to neglect the signs of weakness and fatigue which a normal man would heed, especially as to confess them is to admit to their associates that they are still tuberculous. The removal of waste and fatigue products makes demand upon the same metabolic forces as do the processes of repair, forces which are almost too weak, and whose necessary materials are present in almost too small quantity to cope with the great demands made upon them by the removal and replacement of the extensive diseased tissue. There is competition among the tissues of the body for their necessary repair. The healthier cells are stronger, and the brain and muscle cells will make their demand felt first, then the somewhat weakened heart and abdominal organs, then the tissue around the less active lesions, and lastly, the tissue around the most active tubercles, which is most poisoned. This order is of course modified by the physiological precedence taken by tissues of vital necessity such as brain and heart, when any constituent is deficient in the body. But the first to suffer will be the tissues which surround the most recent and active lesions, the very points where resistance is weakest and where need is greatest. The bodily activity of the patient should therefore be kept at a minimum until sufficient time has elapsed for the physician to believe it possible that reasonably secure healing has taken place around the most recent lesions.

MECHANICAL CONDITIONS AFFECTING TREATMENT.

A complete and symmetrical pneumothorax can rarely be produced. With such a pneumothorax, the entire lung is collapsed into a small kidneyshaped mass situated near the hilum, and of a perfectly regular outline. If a compressed lung still extends to either the diaphragm or apex, or if its outline shows irregular projections, we may be very sure that there are adhesions which prevent collapse. Such adhesions must bear the entire elastic tension of that part of the lung, and it is evident that even slight respiratory movements must greatly alter the tension of the tissue making up the band of adhesions. Tuberculous lesions immediately adjacent to such adhesions are therefore apt to be placed, by the induction of the pneumothorax, under conditions more unfavorable to local healing than they were before. We not infrequently see cases in which the pneumothorax is complete except for adhesions to the diaphragm and near the apex or shoulder. Adventitious sounds are usually heard at the site of these adhesions, and are often explained as pleural frictions. Such adhesions are always under tension and present rounded angles, with the pleural surfaces nowhere in contact; how friction sounds can be produced is difficult to understand. It is much more probable that such sounds are atypical râles, that they indicate that the pulmonary tissue near such adhesions is still being subjected to such violent stresses that râles are produced in spite of the collapse. It is easy and pleasant to ascribe such sounds to adhesions, but a careful scrutiny of stereoscopic x ray plates will, in many instances, show that it is absolutely impossible for friction sounds to be produced in that particular locality.

Owing to the lack of expansion of the collapsed lung, and to its distance from the chest wall, all of the physical signs of disease obtained by percussion or auscultation are suppressed excepting in adherent areas, and the impression given by physical examination is that of complete absence of so-called active disease. Even if actual extension of the disease should take place, we could not detect it by physical examination of the compressed lung. The physical signs have not disappeared on account of the cure of the disease, they have merely been suppressed. A suppression of the physical signs of progressive disease also takes place in the opposite lung, and we regret that the causes of this suppression are usually overlooked in textbooks and special articles dealing with artificial pneumothorax. These causes act in any case in which one lung is limited in its function and the other is compensating, and a recognition of this suppression of physical signs in the compensating lung will sometimes aid us in avoiding mistakes in the treatment of such cases.

It is generally recognized that a compensating lung is hyperresonant. Regions of moderate infiltration are so expanded that moderate dullness may become but slightly impaired resonance, and owing to the greater tension of the tissues, percussion over this slightly impaired area may elicit transmitted resonance from other parts, so that the region may appear to give a normal percussion note. The harsh and exaggerated breathing heard over a compensating lung obscures all but the well marked changes in the breath sounds. Râles are reduced in number or entirely suppressed in a compensating lung; in other words, it requires greater pathological activity in a lesion to produce râles in a compensating lung than it does under ordinary conditions. There are two reasons for this, and they deserve careful explanation and consideration on account of the great importance of the fact. Under ordinary conditions, the diseased regions are breathing to the minimum extent which the reflexes of the body can accomplish, certainly much less than under normal conditions. The compensating lung is fully expanded in every part and breathing at its maximum efficiency. The tidal exchange of air, and therefore the drying of the surfaces of the airspaces, is much greater in the lesion in the compensating lung, and moisture must therefore be exuded at a more rapid rate before râles are produced. The increased flow of blood through the compensating lung, and the increased lymph flow promoted by the increased respiration, both tend to remove poisonous substances more rapidly from the vicinity of the tubercles. We all know that râles are produced, not in the tubercles, but in the inflammatory zone immediately surrounding them; not by the tubercle bacilli, but by the poisonous materials elaborated in the tubercles. If these poisonous products are washed away at a more rapid rate, they must be produced at a more rapid rate in order to maintain enough inflammatory reaction to produce râles.

We must therefore consider that slight physical signs in a compensating lung have many times the significance that the same signs would have under ordinary conditions, and that in such a lung lesions may be present without râles and yet with a degree of pathological activity which would give abundant evidence of moisture in a lung not compensating.

Even the x ray plates are deceitful in case of a compensating lung. The hazy markings and faint clouding upon which we base our opinion of the earliest pathological activity often depend as much upon the partial atelectasis always present in infiltrated regions, and upon the increased moisture of such lesions, as they do upon actual cellular infiltration. In the fully distended and relatively dry compensating lung, it requires more cellular infiltration to produce the same haziness or clouding. In other words, a lesion must be more progressive or more advanced in a compensating lung before it will produce the appearance which the röntgenologist recognizes as indicating socalled activity.

We have seen that both the clinical symptoms and the physical signs are suppressed by artificial pneumothorax to such a degree that they do not even indicate any activity whatever in many cases, and that there is even a reserve of suppression, so that the disease can actually advance to a considerable extent before either clinical symptoms or physical signs will reappear. Almost all of us base our treatment largely upon certain clinical symptoms and physical signs. Some of us rely upon temperature, some upon weight, some upon râles, some upon pulse rate, some upon x ray plates as the chief criterion, of course considering all of these and other indications. But all of these are rendered worse than valueless by artificial pneumothorax; they are made deceptive and misleading. It is but natural that the custom has grown up of treating the patient according to the apparent indications, which means that in a few weeks or months he is allowed to leave the sanatorium and report for treatment. He usually resumes his part in ordinary life in a very short time, and we even read articles upon artificial pneumothorax in which the writers take great pride in the short time in which far advanced cases were returned to gainful work. Such cases are being treated, not for tuberculosis, but for pneumothorax. In many of them the untreated tuberculosis is steadily advancing, and will at last overwhelm the reserve of suppression maintained by the pneumothorax, resulting in a hopeless terminal condition. In the majority the progress of the disease is but slow, it is biding the time when the pneumothorax is lost or discontinued, when it will burst forth again and still farther advanced than it was before the pneumothorax.

On every hand we read and hear the glib counsel to maintain pneumothorax indefinitely. Those who give this advice are first, the inexperienced and thoughtless; and second, those who are older and wiser in the work, and disillusioned. The first class have been but a few years in pneumothorax work, and usually in institutions or resorts. They have seen the first brilliant results, their patients leave for home to continue the treatment, and write occasionally for a year or two. But when the compression is lost, and the break comes, they do not return to the operator. The thoughtless ones are those who blame the patient, some complication or intercurrent illness, or some outside influence, for every pneumothorax which is not continued, and remember only the few cases that they have maintained for several years. The wise ones have learned that the duration of most pneumothoraces is limited, that often intercurrent illness, carelessness of the patient, or social necessity interrupts the treatment, that even if not interrupted, there is in many cases a slow extension of the disease; and that in nearly all, fluid or adhesions sooner or later bring about the termination of the treatment, to be followed by the reawakening of the disease. But they consider that the temporary restoration to a life which is tolerable is well worth the treatment, and they advise the patients to continue it for life, although they well know this will often be impossible.

It has been a most bitter disappointment to us that a treatment which promises so much, and which actually accomplishes temporary results which seem like miracles, should yet be productive of so few permanent cures. The fault lies at least in part in ourselves. We have failed to realize that the disease is suppressed, but is not quiescent in reality. We have unconsciously followed the indications of signs and symptoms which can no longer guide us. On account of the lack of signs and symptoms of socalled active tuberculosis after artificial pneumothorax, we have stopped giving treatment for tuberculosis, and have merely maintained the pneumothorax. Artificial pneumothorax creates conditions which are incomparably more favorable for the recovery from tuberculosis than those which existed before. Given proper treatment for the disease, it should be followed by a much greater number of recoveries. But it is not sufficient to entirely replace the treatment of the disease, and this is exactly what it is ordinarily expected to do. In the class of cases in which it is induced, the healing of the lesions under the most favorable circumstances would take at least two years. It is doubtful if pneumothorax can be maintained in the average case for a longer period. If we devote this period to a treatment of the disease instead of an effort to return the patient prematurely to full participation in active life, there is every likelihood that we can restore most of the patients to a condition far better than that which they now attain.

The special care which a patient should have during the reexpansion of the lung has been discussed in another article. It may not be out of place to briefly restate in this lecture that during the period that the lung is reexpanding, it is subjected to unusual stresses and strains, and that during this period the patient should be closely watched; at the slightest indication of toxemia, such as nervousness, irritable heart, loss of appetite, insomnia, and other symptoms the patient should be placed at rest. The ideal would be to carry out a series of more delicate tests during this period, such as functional heart tests, and others.

SUMMARY.

1. Artificial pneumothorax produces in suitable cases of tuberculosis the most brilliant improvement. Up to the present time this improvement has been but temporary in the vast majority of cases.

2. Artificial pneumothorax is not a treatment of tuberculosis, but is merely an adjunct to treatment.

3. After pneumothorax the clinical symptoms of tuberculosis are suppressed before there is any real progress toward cure, and consequently are not only worthless, but actually misleading as guides to treatment.

4. The physical signs of socalled activity are suppressed both on the compressed side and in the compensating lung, and may not reappear until the disease has made more progress than would be required to cause marked signs in an ordinary patient.

5. The physician should constantly keep in mind the principles of immunology upon which these suppressions depend, and should remember that the usual guides to treatment, based on clinical symptoms and physical signs, fail entirely in cases of pneumothorax.

6. Any patient who has been given artificial pneumothorax should continue to receive a treatment for tuberculosis which would be adequate for the pathological condition which is present, and which would undoubtedly be given if the physical signs and clinical symptoms were not masked by the pneumothorax.

NOTE.

During the past three years the principles outlined have been more or less thoroughly applied to certain of the patients treated by artificial pneumothorax at New Haven. The time has been too short, and the cases too few, for the submission of either case reports or statistical data. But a comparison of the results of such treatment with those attained in patients who, after their clinical symptoms had become slight or none, followed a régime suited to their clinical symptoms rather than to their pathological conditions, indicates strongly that these principles will, if carried out, result in a greatly increased proportion of permanent benefit from artificial pneumothorax.

Reflections Upon Nine and One-Half Years' Experience With Artificial Pneumothorax*

By PAUL H. RINGER, M.D.,
Asheville, N. C.

In 1917, my partner, Dr. Charles L. Minor (1), read a paper before this section on four and one half years' experience with artificial pneumothorax. In it he reported upon a hundred cases in which an attempt had been made to compress the lung. It is my purpose today to glance back over our pneumothorax work done during the past nine and a half years and to see what impressions and conclusions can be reached as a result of constantly growing experience with the procedure.

It is no longer necessary to dwell in detail upon the indications for artificial pneumothorax. We find, however, that we are likely to try pneumothorax in milder cases than formerly, in those cases where the patient is stagnating instead of going definitely down hill, or in those cases where a relatively small area of disease shows signs of increased activity or of spread. The following recent case is a good illustration of rapid increase in activity in a patient with slight physical findings and symptoms.

Case.—Miss K., under treatment eight months and doing well, on January 22, 1922, began to have slightly streaked sputum and finally had small hemoptyses. Physical signs increased, cough and expectoration as well, x ray showed corresponding changes and she began to have a febrile temperature. On February 22 pneumothorax was started. Excellent collapse was obtained with disappearance of all symptoms of cough, sputum and temperature (Fig. 1). Now her condition is excellent. We are also more likely to try pneumothorax as a purely palliative measure in the hope of giving the patient comfort and relief.

Cases with apical involvement offer a better outlook for satisfactory compression than do cases with basal disease because partial collapse, so often beneficial as will be pointed out later, is far more apt to be possible when the main seat of trouble is at the apex.

Cases of profuse hemorrhage give us some of our most brilliant results in artificial pneumothorax, as in this form of treatment we possess the only direct means of arresting hemoptysis.

The technic has become more simple, and the process of giving injections less formidable than of yore. We find the preliminary injection of morphia almost never necessary. Occasionally a dose of aromatic spirits of ammonia or of codeine has to be given after the injection.

Atmospheric air has been used exclusively. It works just as well as the nitrogen we so conscientiously used for years. We have not seen any benefits from using the warmed air recommended by some authors.

One point in the technic of injection has proven of value in my hands. It not infrequently happens at a first injection, that the proximal arm of the manometer will show a marked negative reading without fluctuations, when one feels almost certain that the point of the needle has penetrated the parietal pleura. If the needle is gradually withdrawn it is felt to slip out of the pleural cavity and the manometer falls to zero. I believe that this high negative, nonfluctuating reading denotes that the point of the needle is resting against the visceral pleura. When such condition presents itself, if a minute amount of air (as much as can flow through the needle when the air cock is opened for between a tenth and a fifth of a second) is allowed to flow, the visceral layer of pleura is pushed away from the point of the needle, and the characteristic free negative manometric fluctuations at once set in. I have noted this so many times that it cannot be merely a coincidence. The procedure is not dangerous in any way, and is of value in creating a pleural space.

---

*Read in the Clinical Section of the National Tuberculosis Association, Washington, May 4-6, 1922.

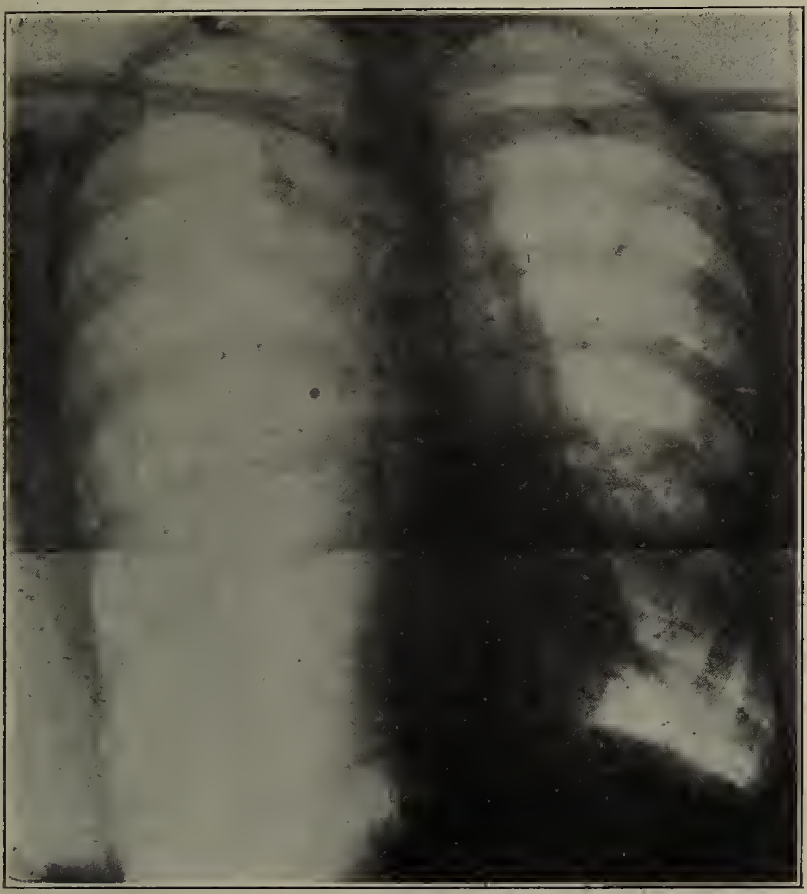

FIG. 1.—Patient after compression, left side.

Refills are more frequent and less massive than they used to be several years ago. The more I see of pneumothorax the more satisfied I am of the advisability of this principle, based on the comfort and safety of the patient. Riviere (2) says: "It is not wise to let refills run above seven hundred or eight hundred c. c. and in most cases five hundred c. c. or less is a preferable amount." I find myself absolutely in accord with him. By allowing too long an interval between refills not only is excessive mediastinal shifting brought about, but the formation of adhesions in the costophrenic sinus is favored, which may easily become the starting point for obliteration of the pleural cavity. In the past three years I have had but two cases under my care that were allowed to go more than twenty-one days between refills.

In hemorrhage cases alone do we find justifications for the use of massive injections. I have given one thousand to fourteen hundred c. c. at the first injection. Here, where we wish to squeeze down the lung sufficiently to occlude the bleeding point, small doses are useless, and may even prove harmful in a manner analogous to the tourniquet that is placed about a bleeding limb sufficiently tight to impede the venous return but not to cut off the arterial influx.

PRESSURE.

As a rule the final air pressure as recorded by the water manometer need not be over plus four cm. Occasionally, as when a cavity remains persistently open, and it is believed upon fluoroscopic and radiographic examination that the adhesions can be stretched, higher pressures, up to eight or ten cm. of water are permissible. In one case, not long ago, I erred in not pushing the pressure up. The patient passed out of my hands, and a colleague, profiting by my mistake in judgment, greatly increased the pressure and finally succeeded in compressing an apical cavity and in obtaining a total collapse.

I cannot protest too strongly against the practice of using high pressures with the object of tearing adhesions. This is most risky, as it is not known whether blood vessels are in the adhesions, and Jacobaeus (3) reports his only alarming experience as resulting from profuse hemorrhage occurring in the course of the cauterization of an adhesion. Furthermore, it cannot be foretold at which end the adhesion will tear if it does give way. The visceral extremity may tear, and in so doing lacerate the lung causing severe hemorrhage with a resulting hemopneumothorax. It is safe to stretch adhesions gently, but not to submit them to excessive tension.

The accidents incident to artificial pneumothorax seem to be becoming fewer and fewer. A search of the literature reveals but one or two reports of untoward occurrences. Those bugbears, pleural shock and air embolism are becoming curiosities rather than dangers. Since the spring of 1919, I cannot remember a single alarming symptom appearing during or immediately after an injection. My experience, I am sure, will be duplicated by practically every worker in this field.

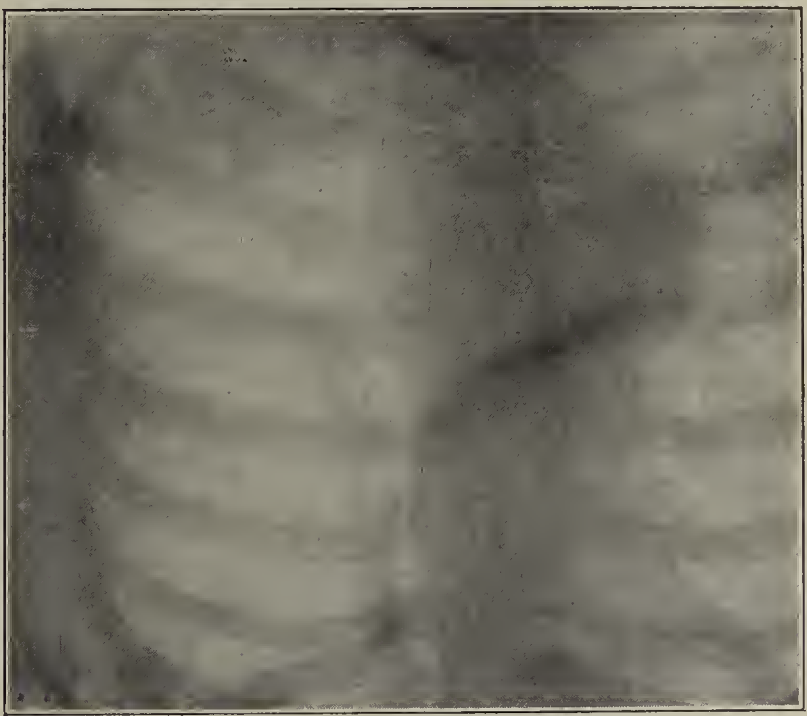

FIG. 2.—Attempted pneumothorax, left side. Absolute failure.

I believe the reasons for this satisfactory condition of things are twofold:

1. Better anesthetization of the field of injection

especially of the pleural membrane itself. This I feel is important. If patients are not hurt they will not exhibit many of the purely nervous reflexes that formerly were attributed to the mechanical injury sustained at the moment of injection. It is asserted moreover that the reflexes causing pleural shock arise from the visceral pleura where there is luxuriant arborization of filaments from the pneumogastric nerve. If this theory be true the necessity of careful pleural anesthesia becomes all the more apparent, as at any first injection the visceral pleura is almost certain to be touched.

2. Better manometric interpretation. Unless the point of the needle penetrates the wall of a cavity and in so doing lays open the lumen of a vessel into which air from the lung can be aspirated with each respiratory excursion, prior to any air having been allowed to flow from the pneumothorax apparatus, there is no excuse for air embolism if the manometric readings are strictly observed and their simple meaning correctly interpreted.

CHANGES OF SUCCESS AND FAILURE IN ANY GIVEN CASE.

There is nothing in which I have less faith than in my ability to foretell whether I will be successful in establishing an air space at the initial injection. When all is said and done, when stereograms have been taken and studied, when the respiratory motion of the pulmonary bases has been estimated and observed by percussion and under the fluoroscope, when the patient had been carefully auscultated and the presence or absence of pleural frictions determined, chances of success are very uncertain. I am glad to see my opinion thus corroborated by Boas (4): "Physical signs and fluoroscopy will not always give assurance whether or not collapse of the lung is possible. In many cases all efforts to enter the pleural cavity are unavailing although no difficulty is expected." The three accompanying figures illustrate this point well.

TOTAL AND PARTIAL COLLAPSE.

Were benefits derivable from artificial pneumothorax to depend upon total collapse, the method would have been loooked upon as so rarely of service as to hardly warrant its general use. Fortunately partial collapse is productive of great good. Some of the cases showing most striking results have done so as a result of partial collapse only.

No better illustration of this fact could be given than the following case of Mrs. C., who had bilateral involvement, by far most marked on the right, with temperature to 102°, a really terrible cough, much sputum, emaciation, night sweats, all the classical symptoms of advanced progressive tuberculosis. As a last resort artificial pneumothorax was tried. The result was miraculous. The temperature dropped, cough was greatly lessened as was sputum, appetite returned, and in every way marked improvement ensued. Now, one year after collapse, while not well, she is perfectly comfortable, goes about the house, can take motor rides, and is able to enjoy life.

To be sure, partial compression will not bring about such total disappearance of symptoms as will complete collapse, but partial compression will very frequently do away with the symptoms of toxemia such as fever, night sweats, anorexia, and other symptoms. The reason for this appears to me to be that often the site of greatest toxin absorption is not from the walls of a cavity but from the pericavernous lung tissue. This tissue will frequently be well compressed while dense adhesions prevent the cavity from closing. Partial collapse proves of more service when the adhesions limiting it are apical rather than mesial or basal. The method of Jacobaeus of cauterizing adhesions and thus converting partial into total collapse holds promise.

Bilateral compression has from time to time been mentioned in the literature. It has been mentioned as being done simultaneously, and also as being done successively first on one side and then on the other at an interval of a few weeks or months. I have never been able to convince myself of the justifiability of this procedure and have never seen a case in which I was even tempted to try it. It has always struck me as riding a good horse to death, and as coming under the head of meddlesome interference.

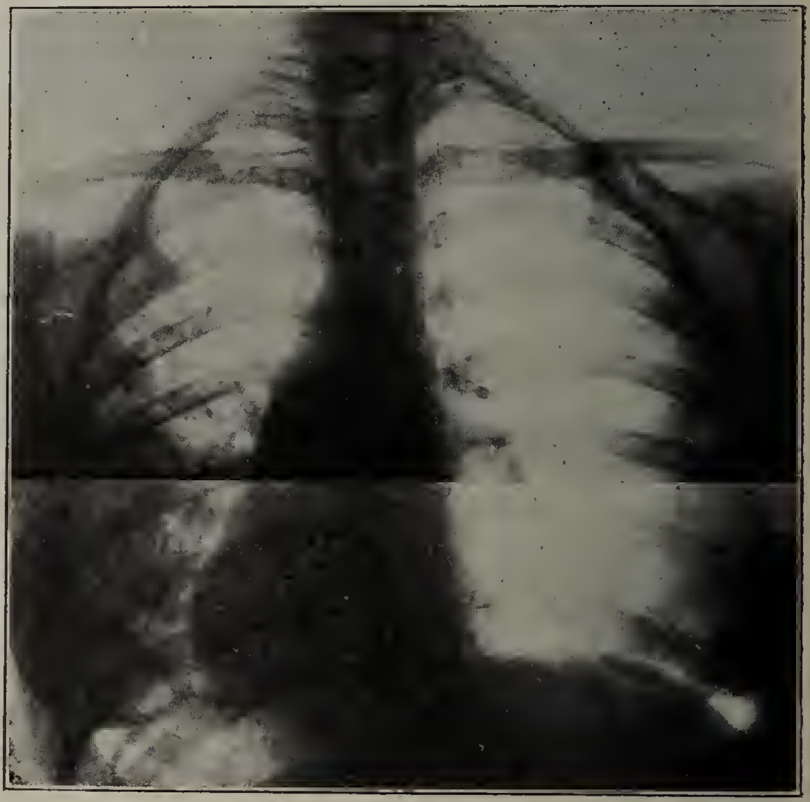

Fig. 3.—Attempted pneumothorax, left side, no difficulty in securing compression. Picture before compression was attempted.

COMPLICATIONS.

The most frequent complication met with and the one that at present is offering the greatest subject for discussion and controversy is fluid.

Our views with regard to the appearance of fluid in the course of an artificial pneumothorax have undergone great modifications in the past few years. Its presence used to be looked upon as a beneficial occurrence, helping to preserve the collapse, lessening the frequency of refills, and, save when becoming infected, productive of no harm. But with added experience, many cases are constantly seen that, where fluid developed, henceforth do not get along as well. The great harm that fluid does is to favor the gradual obliteration of the pleural cavity from below upward, and to draw the mediastinum over toward the treated side. In an excellent paper read before this section last year, Stivelman and Rosenblatt (5) laid down the principle that in many cases the expectant form of treatment of fluid is not justifiable. In our work I have not encountered fluid as frequently as have many other observers. The common consensus of opinion is that it occurs in about fifty per cent. of the cases. I regret that my records are incomplete on this score, but I am certain that I have not encountered fluid in over twenty-five per cent. of the cases, unless one counts the ounce or two that often accumulates in the costophrenic sinus, that shows no tendency to increase, and that can be discovered only by the x ray. In my experience these minute quantities of fluid do no harm. As I wrote in 1917 (6), I have for several years made it a practice to always aspirate any fluid reaching the fourth rib, and to substitute air. I have done this even in the absence of signs of retraction of the pleural cavity or of mediastinal shifting toward the treated side, which is the indication given by Stivelman and Rosenblatt. I do not differ with their indication in any way. The reason I have not followed it is that my work not being under one roof, the bringing of patients to the office every time for röntgenological examination often proved too fatiguing for them.

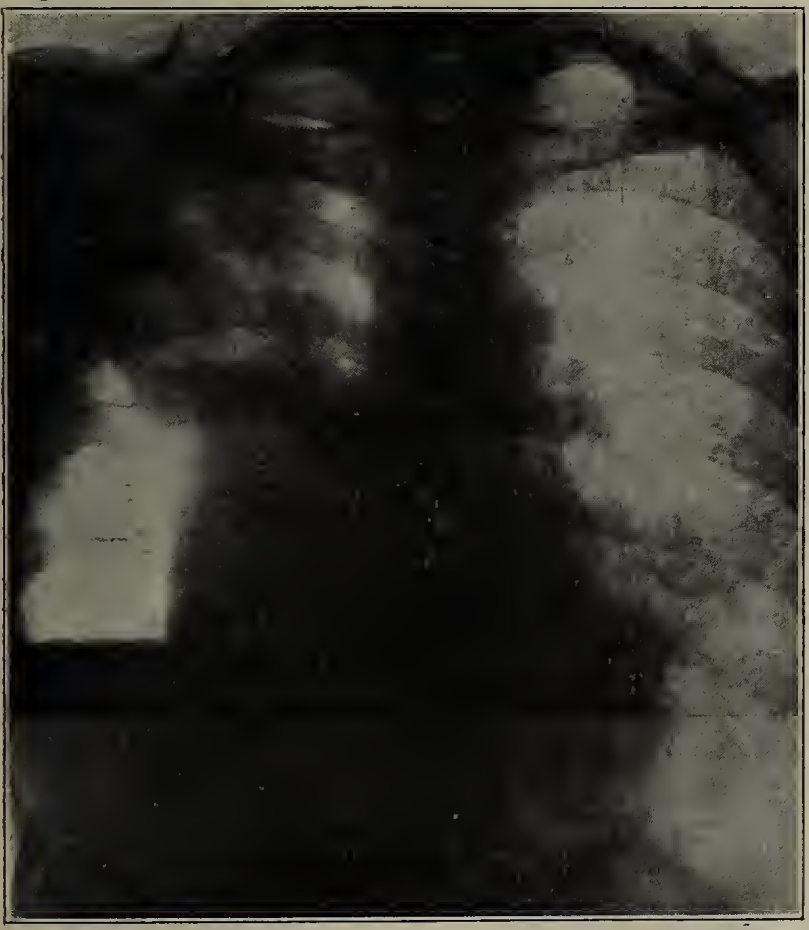

FIG. 4.—Partial compression with remarkable clinical result.

As a corollary to this method of dealing with fluid, may be noted the marked tendency at present to substitute air for fluid after thoracentesis in cases of pleurisy with effusion.

APPEARANCE OF OR INCREASE IN ACTIVITY IN UNCOLLAPSED LUNG.

This unfortunate complication is met with not infrequently by all doing much artificial pneumothorax work. The more careful one is in the selection of cases the rarer will be its occurrence. I am, however, of the opinion that in those cases in which artificial pneumothorax can be considered, and in which, unless collapse is obtainable, the outlook is absolutely bad, the risk should be run and the patient given the chance, for occasionally surprisingly good results will be obtained in cases showing both radiologically and on physical examination evidences of considerable activity in the relatively good side. These patients can often be helped and their remaining days made more comfortable.

DURATION OF COLLAPSE.

This important question is a difficult one to decide. In too many cases complications will decide it for us by forcing the discontinuance of injections. If no complications occur, the cases fall into three groups: 1, Cases with total collapse; 2, cases with partial collapse, and 3, cases collapsed for hemorrhage.

CASES WITH TOTAL COLLAPSE.

In my opinion collapse should be maintained for at least two years and even longer. We have no way of telling when healing is complete, and a perfect collapse is too valuable an asset to be lightly dispensed with. Postmortem findings in such cases are too infrequent to permit of the formation of conclusions as to the time element necessary for permanent healing. Refills can now be so universally obtained that the question of the patient having to stay in one place does not enter into the matter. After two years or so it seems reasonably safe to allow reexpansion.

CASES WITH PARTIAL COLLAPSE.

These patients should be refilled indefinitely. The compression is not such as to bring about complete healing and the benefit derived from compression is to be obtained only as long as it is maintained. If it is released, evidences of activity will almost invariably set in.

CASES COLLAPSED FOR HEMORRHAGE.

This class of cases can further be subdivided into two: a. Cases in which the opposite lung is free from disease; b, cases in which the opposite lung is more or less involved.

We not infrequently see patients exhibiting profuse hemoptysis in whom we had not considered artificial pneumothorax prior to the advent of bleeding despite the fact that the process was wholly or mainly unilateral. If forced to collapse the lung to control hemorrhage, the collapse should be continued as though it had been begun in the absence of any emergency, as thus both subsequent bleedings will be avoided and new areas of involvement as a result of the hemorrhage will be nipped in the bud. In cases in which the opposite lung is more or less involved collapse should be maintained only until such a time as we feel reasonably certain that the bleeding point is firmly plugged. I know of no guiding rule. I have, however, found, purely by experience, that from three to four weeks is a sufficient length of time to maintain the collapse which should be kept under rather higher pressure than when done in the absence of hemoptysis. Needless to say, as this class of cases is unsuited for pneumothorax and the procedure is an emergency measure, the sooner the added strain upon the uncollapsed lung can be removed, the better.

ARTIFICIAL PNEUMOTHORAX IN ABSCESS OF THE LUNG.

My experience in this class of cases is small but at the same time most unsatisfactory. The one brilliant result that we obtained was, I think, back in 1912 in one of the first cases Dr. Minor and myself ever did. A dying man was converted in a few weeks into a healthy vigorous individual who resumed his work and was eventually lost sight of. Other cases stand out in my memory in a very different light. In one a lung abscess that was being compressed burst into the pleural cavity with resulting death of the patient. In another practically the same thing occurred. In still another compression did no good and the patient eventually recovered, after having reached the brink of the grave and refusing surgical intervention, by the providential spontaneous rupture of the abscess into a bronchus. All in all I am not in favor of attempting to squeeze out an abscess of the lung by artificial pneumothorax. It is too much of a hit or miss method. Surgery is much better. Cases of lung abscess seen really in their incipiency offer a much better chance of cure by compression than do those seen when fully established. I have not had the opportunity to try compression upon any early cases.

Brilliant though immediate results frequently are in cases treated with artificial pneumothorax, the cold light of statistics shows that the percentage of permanent complete recoveries obtained is disappointingly small. Boas, from an experience of six years at the Montefiore Home, confesses frankly that "positive cure is too rarely accomplished. Generally marked improvement sets in for a time, and then some complication supervenes which causes the disease to resume its course. The patient often gets a reprieve of a year or two, and this means a good deal."

I would not be thought, as a result of almost a decade of experience, to consider artificial pneumothorax as of little avail. In some cases it will actually drag a patient out of the grave and restore him to permanent and complete health. In many cases it will help—will inhibit the advances of disease and will prolong life—but a glance at the tabulation of any fairly large number of cases covering a few years will show that by far the greater number are either dead or wholly incapacitated. Nevertheless, artificial pneumothorax succeeds in a sufficiently large percentage of cases to warrant its continued use, together with constant searching for better technic and improved methods to make the procedure more complete.

In his paper in 1917, Dr. Minor reported on one hundred cases of attempted artificial pneumothorax. Of his hundred cases, in eleven no entry was possible, and forty-four were classified as failures mainly because of the presence of adhesions. I wish to report on 101 cases occurring in our practice in which at least partial collapse was obtainable, thus eliminating the failures in the sense of no pneumothorax being obtainable.

I have divided these 101 cases into five classes: Dead, dying, living, well, and unknown.

By living I mean still in fair condition, but pursuing their cure and incapacitated from work. By well I denote those that have achieved a symptomatic and economic recovery.

TOTAL CASES—101

Dead	*Dying*	*Living*	*Well*	*Unknown*
41	5	25	14	16

Eliminating the unknown class, there are left eighty-five cases upon which to base our results.

Dead	*Dying*	*Living*	*Well*
41 or 48.2%	5 or 5.8%	25 or 29.4%	14 or 16.4%

The five cases in the dying class if added to the dead class make a total of fifty-four per cent. as practically dead.

Among the fourteen classified as well, three deserve special mention. Two patients recovered not because of, but despite their pneumothorax. In one not the slightest effect was produced, and another was a case of lung abscess which finally ruptured spontaneously after artificial pneumothorax had been abandoned and surgery refused. The third patient, still under treatment, is a most remarkable one of spontaneous pneumothorax in an individual never having shown any symptoms of tuberculosis. The lung has expanded twice, only to have the pneumothorax recur. It is now being held down in the hope that the opening will permanently heal. Thus, subtracting the three cases just mentioned, there are but eleven, or 12.9 per cent. of the eighty-five cases, that owe their recovery to artificial pneumothorax, not a large percentage when we consider that these 101 cases were all individuals in whom at least a workable collapse was obtained. Twenty-five others, however, are still living, and of these twenty-five, sixteen, while incapacitated from work, are enjoying fair health and are not bedridden invalids. This brightens the picture. Thus out of the 101 cases fourteen are well and sixteen able to lead a life limited, it is true, but still not that of one hundred per cent. invalidism. This gives an aggregate of practically thirty per cent. showing marked improvement and freedom from absolute invalidism, surely a number amply justifying the use of artificial pneumothorax.

To epitomize briefly conclusions reached as a result of nine and one half years' experience with artificial pneumothorax, it can be said that the method is distinctly valuable, and one which no man devoting himself largely to pulmonary tuberculosis can afford to neglect. Its applicability will of course vary with the personal opinion of each one that uses it. To some the field will widen, to others it will contract. Immediate results are often surprisingly brilliant; the percentage of really permanent arrests disappointingly small. Its use in hemorrhage is of the greatest value. It is often an immediate life saver, frequently a life prolonger, not seldom a bringer of comfort and relative relief from distressing symptoms. Finally it is the one method at our command that offers to the far advanced unilateral or relatively unilateral case a good chance of further longevity, and a reasonable chance of economic recovery.

The Value of the Röntgenogram in the Diagnosis and Prognosis of Pulmonary Tuberculosis*

By GEORGE G. ORNSTEIN, M.D.,
New York.

The use of x rays in the diagnosis of diseases of the lungs has placed in our hands a valuable aid to the early diagnosis of pulmonary tuberculosis. In the last few years with an improvement in technic and better interpretation of shadows, question as to the value of röntgenograms in disease of the thorax has ceased. The more uniform technic and comparison of x ray shadows with autopsy findings have helped to clear up many of the differences in opinion in interpretation that previously existed.

Before discussing x rays in pulmonary tuberculosis, perhaps it be best to go through a few of the simple rules of physics which may help us in understanding the seemingly difficult problems which frequently occur in the interpretation of röntgenograms of the lung.

PHYSICS.

The shadows appearing on the x ray plate are dependent upon the ability of substances to absorb the rays from the target of the tube. The rays, going through a substance of uniform density, will throw a homogeneous shadow, varying only in that the area over which the tube is centered is more distinct than that of the periphery. If, however, in this very substance, there are areas of greater density, the shadows thrown by these areas will be more intense than those of the substance itself. On the other hand, if there be areas of lesser density, it naturally follows that the shadows thrown by these areas will be less intense. This principle also holds true in röntgenograms of tissues. If, in normal areas, pathological changes occur, more or less intense shadows will be cast, depending upon whether the density of these pathological areas is greater or less than the density of the surrounding normal tissue. We can therefore see that pictures of normal areas have definite standards, and if changes occur which either increase or decrease the densities of these areas to an appreciable degree, they will be noted in the röntgenogram. It is particularly fortunate that in radiography of the pulmonic area the structure of the lung is of such nature that very slight changes in density can be recognized by their contrast with the air containing lung tissue.

TECHNIC.

In the technic of taking the plates lies the cause of most of the differences of opinion as to the value of the röntgenogram. Faulty technic invariably leads to incorrect interpretation.

Depending upon the thickness and density of the part to be x rayed, either a soft or hard tube is used; the harder the tube the greater its penetration. For example: if tissues or small bones are to be rayed, a soft tube should be used; for areas of greater density a hard tube is the choice. The important thing is to have a tube that has penetration enough to go through the depth of the part to be x rayed. If the penetrating power is too little, cloudy and exaggerated shadows are shown. If the penetrating power is too great, a diminished shadow is shown and the fine detail that is necessary for a good reading is lacking. We can readily see how much depends upon correct technic for proper interpretation.

NORMAL APPEARANCE OF THE LUNG.

It is of the greatest importance that the x ray be used with a clear appreciation of what are the normal appearances of the lung. Röntgenographically, the lung may be divided into hilus, bronchial tract and parenchyma. A clear perception of the appearances of these divisions is absolutely essential before pathological changes can be recognized. The normal shadows of the hilus of the lung have brought forth much discussion. At first these shadows were accredited to early tuberculosis. This view was quickly discarded. Investigators were divided in their beliefs that the shadows are due to bloodvessels and lymphatics or bronchi. The accepted view is that they are due to both the vessels and bronchi. The shadows are accentuated where a vessel or bronchus crosses a rib or where vessels or bronchi cross each other. Normal glands are not visible in this area. Healed tuberculous glands are common and fibrosed and calcified glands are often seen. The hilus shadow is well marked on the right side, but hidden on the left by the shadow of the heart. Radiating out from this root region, in fanshaped fashion, are the divisions of the bronchi and the vessels. Attention is brought to the bronchial trunks going to the upper third of the lung. In the upper third of the lung the vertebral branch and the branches to the first and second interspaces can be followed until near the periphery of the lung, where they appear as fine lines and are lost in the parenchyma. The bronchial shadows are continuous and here and there exaggerated by intersection. The parenchyma of the lung does not cast shadows.

PULMONARY TUBERCULOSIS.

Cole (1), in 1908, was the first in this country to insist that an early tuberculous lesion of the lung could be diagnosed by röntgenography. He ably set up standards for the shadows of the socalled tubercle, not the pathological tubercle that is microscopic, but a definite amount of tuberculous deposit of sufficient size to be noted at the autopsy table. This shadow Cole named tubercle and larger shadow conglomerate tubercles. He further stated that these tubercles, if seen along the course of the bronchi or in the parenchyma, could safely be called tuberculous. His work has stood through these years. The tubercle shadows are difficult to describe. They are more easily demonstrated on the plate. They have been given many descriptions. A few of the popular ones are cloudy, tobacco smoke, cotton ball, and mottling. The last two are perhaps the better terms. The intensity of the shadows is absolutely dependent upon the density of the tubercle and varies from the recently formed tubercle, which has a soft cottony appearance with its margins merging into the adjoining parenchyma, to the calcified and fibrous tubercles which cast intense shadows and have well defined margins. Caseation, consolidation and cavity formation will vary the picture, the first two throwing intense shadows while the last mentioned shows the rarefaction that is so characteristic of cavity formation.

---

*From the Department of Tuberculosis, Vanderbilt Clinic; Medical Department, Columbia University. Read before the Association of Tuberculosis Clinics, Academy of Medicine, New York, November, 1921.

CLASSIFICATION.

Tuberculosis of the lung from a röntgen point of view may be divided into groups dependent upon anatomical position; that is, whether it involves the hilus, the bronchial trunks, the parenchyma or a combination of any of these. It may be again divided into minimal, moderately advanced or far advanced, depending upon the extent of the lesion. The character of the lesion may also give one an idea as to whether or not an active or inactive condition exists.

HILUS TUBERCULOSIS.

In hilus tuberculosis we see something more extensive than in the normal picture, in which we see shadows more or less diffuse with a few calcified or fibrous tubercles. The hilus shadows now extend out more. Tubercles are more numerous and may extend out from the root into the parenchyma. We must not overlook the fact that other conditions may cause shadows in this area, particularly pneumonoconiosis, such as anthracosis from coal dust, chalicosis from stone and siderosis from iron. The fuzzy outline of the tuberculous shadows help considerably in the differentiation.

PERIBRONCHIAL TUBERCULOSIS.

Peribronchial tuberculosis shows a thickening of the bronchial trunk with tubercles to be seen here and there along its course. In places the tubercles may extend out into the parenchyma. The vertebral trunk and those of the first and second interspaces are the ones for which tuberculosis has a predeliction. The process as a rule can be traced up from the hilus. I may state that this type of tuberculosis is confined chiefly to the upper half of the lung.

PARENCHYMATOUS TUBERCULOSIS.

The parenchymatous type requires little description. If present, one has little difficulty in seeing it. Invariably a parenchymatous lesion is confined to the upper half of the lung. Tuberculosis of the base is seen only occasionally. When tubercles can be demonstrated in the parenchyma of the lung and are situated in the upper half of the lung, do not hesitate in making a diagnosis of tuberculosis.

EXTENT OF LESION.

The extent of the lesion may be best classified in the manner put forth by Brown, Heise, and Sampson (3). Their classification is as follows:

1. Incipient or minimal tuberculosis in which x ray findings to show a total area involved not greater than the area to the upper level of the second chondrosternal junction on one side in the form of scattered mottling, or an intense shadow interpreted as pleuritic.

2. Moderately advanced where x ray findings show an intense shadow, not interpreted as pleuritic, of no greater extent than the area above the upper level of the fourth chondrosternal junction on one side; or area of rarefaction interpreted as cavities limited to one interspace; or scattered mottling over a greater area than under minimal, but not greater than the area of one entire lung and to the level of the second chondrosternal junction on the opposite side.

3. Far advanced: The x ray to show an intense shadow, not interpreted as pleuritic, of greater extent than the area to the level of the fourth chondrosternal junction, or areas interpreted as cavities, greater than one interspace, or scattered mottling greater in extent than under moderately advanced.

DIFFERENTIATION.

That röntgenograms of the lungs showing tuberculous involvement may be very easily confused with other pathological conditions of the lungs has been unnecessarily exaggerated. The pathological conditions from which a differentiation may have to be made are pneumonoconiosis, syphilis, pulmonary abscess and various tumors of the lung. Before differentiating them we must remember that, although we are dealing with shadows, these shadows are thrown by pathological areas that have certain characteristics either in structure or location.

DIFFERENTIAL DIAGNOSIS.

Pulmonary tuberculosis may be confused with pneumoconiosis. The points of difference are that tuberculous infections occupy the apical regions while in pneumoconiosis the subapical regions are involved. Tuberculosis is not evenly distributed throughout both lungs but is apt to involve one lung more than the other. The shadows in pneumonoconiosis are more uniform in intensity, have sharper margins, are larger in size and are more evenly distributed, extending out from the roots almost equally from both sides. The two conditions are often found together.

Recently a considerable number of men have asserted that syphilis of the respiratory tract exists more frequently than the facts show. Before trying to make a differentiation I wish to quote the following postmortems (4): At Johns Hopkins Hospital, out of 2,800 postmortems, twelve cases with syphilitic disease in the lungs were found, of which eight were congenital and four acquired; Lord (5) reports that out of 3,000 autopsies at the Massachusetts General Hospital only one case of acquired syphilis was found; at Bellevue, Symmers (6) reported 4,880 autopsies of which there were twelve cases of syphilis of the lung.

Syphilis of the respiratory system attacks the trachea bronchi, hilus and base of the lung. We will not consider the congenital form. In the acquired, two varieties are found, the gummatous and interstitial. The gummata may vary in size from a hazel nut to a small sized orange. Gummata have a definite shape and are invested with dense fibrous capsule. They are found chiefly in the interstitial tissue. They rarely break down into cavity formation, but form a dry cheesy mass which finally becomes converted into fibrous tissue. The more common form is the interstitial form. It attacks the hilus and descending bronchial trunks to the base of the lung. The type of lesion is an intense fibrotic infiltration. Another type of the interstitial form is an infiltration of all the bronchial trunks throughout the lung.

Recently I have been impressed with a number of cases referred to the Vanderbilt Clinic as probable pulmonary tuberculosis. Clinically they have all the earmarks of an incipient tuberculosis. The largest number give a history of recent hemoptysis. A severe dry cough but often a cough with expectoration, accompanied with a slight rise in temperature, general feeling of malaise and loss of weight are the symptoms of the remaining number. Both groups have very scanty physical findings. Repeated sputum examinations are negative. Though the x ray films absolutely rule out pulmonary tuberculosis the similarity of the films in this group of cases is striking, in that there is some enlargement of the transverse arch of the aorta and that the bronchial trunks to the base of the lungs are markedly exaggerated due to a fibrotic infiltration. In the majority of the cases there is some history of luetic infection and some had a positive Wassermann reaction. Under specific treatment most symptoms clear up and the general condition of the patient improves. This group of cases may be regarded as probable syphilis of the lung. If this group could be definitely proved to be specific in origin perhaps the diagnosis of many cases of peribronchial tuberculosis will have to be changed.

Tuberculosis involving the parenchyma of the lung is not to be confused easily with syphilis of the lung, not only on account of its location but also due to the character of the lesions which are different in type. A positive Wassermann reaction along with a röntgenogram showing a lesion in the lung does not mean syphilis of the lung. And it is also to be remembered that tuberculosis is often found in syphilitic patients.

Pulmonary abscess, whether multiple or single, cast shadows atypical of those cast by the pathological areas in tuberculous infections. The shadow is more or less homogeneous with a bit of rarefaction in the centre. If it opens into a bronchus part of the contents of the abscess may be expectorated, and air then comes into the cavity. The abscess may now show a definite fluid line. Though an abscess may occur in any part of the lung, they are found chiefly at the base or centre. A careful history laying stress upon whether the condition followed a tonsilectomy insufflation of any foreign body, unresolved pneumonia, or other condition, will help considerably.

Tumor shadows are so different from the shadows cast by tuberculous areas that a differentiation is not necessary. The history and clinical findings will help considerably in the differentiation in all the above conditions.

DETERMINATION OF CLINICAL ACTIVITY.

In a preliminary study Sampson and I (6) attempted to determine clinical activity from röntgenograms. The work was based on the relationship of circulation to the tubercle. When the tubercle was healed or walled off by either calcification or fibrous infiltration it was cut off from the circulation. No absorption of toxic substance was possible and therefore no constitutional symptoms forthcoming. From the röntgenogram it is possible to determine whether a tubercle is walled off or not. The intensity of a shadow is directly proportionate to the density of the tissue x rayed. Therefore, tubercles cast various shadows from the new formation of tubercles which appear soft and cottonlike, with margins that merge into the parenchyma of the lung to the healed tubercle that appears intense, with sharp definite margins. When the former picture (new tubercle formation) can be demonstrated in the röntgenogram we can be reasonably certain that both pathological and clinical activity are occurring. Assuming that this soft cottonlike appearance with illdefined margins merging into the parenchyma of the lung indicates activity, as the disease retrogresses, the lung tissue surrounding this area appears to become better aerated and at the same time we realize that the original shadow is smaller or more compact. As time goes on and the patient is doing well, the mottling loses more of its collateral haziness, the cottonlike shadows become more compact and their appearance more discreet, the ray filtering through areas that were previously hazy and the picture is that of a better aerated lung.

As a rule further retrogressive changes occur in this group. This group is clinically inactive. Sampson and I, basing our interpretation of clinical activity on the appearance of new tubercle formation, compared the x ray diagnosis with the clinician's diagnosis of clinical activity and inactivity. The results were as follows: Out of one hundred cases, eighty-seven agreed with the findings of the clinician. Out of twenty-six cases diagnosed active by the clinician, the x ray called twenty-one cases active and five cases inactive. The course of the five cases were inactive. Out of seventy-four cases called inactive by the clinician, sixty-six cases were diagnosed inactive by the x ray and eight active. Out of the eight cases the course of six were inactive and two active. The course of the disease was as a rule the same as that of the x ray interpretation of activity or inactivity. These two columns agreed in ninety-one per cent of the cases.

PROGNOSIS.

From the above it can easily be seen how the x ray may be used in the prognosis of the disease. Particularly in the cases where it is not possible to procure accurate clinical data so necessary for the making of a diagnosis of activity or inactivity of a case. It has also been shown that the course of the disease is usually that of the x ray interpretation, of activity or inactivity. And on this determination, especially when backed by a clinical interpretation the outline of treatment may be based. As for example—in the clinical active—the complete rest cure, whereas in the inactive, the allowing of certain liberties. The value of the röntgenogram is also of great service in comparing films of the past with those of the present in determining whether a lesion is progressing or retrogressing.

CONCLUSION.

In concluding I wish to state that the x ray examination is perhaps unnecessary as a means of diagnosis in the frank case of pulmonary tuberculosis which not only presents the history so characteristic of the disease (hemoptysis and wet pleurisy) but also the symptomatology and the physical findings. The value of the röntgenogram in such a case will be for the extent and character of the lesion. It is also of value as a record when in the future a plate is again taken to determine whether the lesion is progressing or retrogressing. In cases in which the history is obscure and the physical findings scanty and indefinite, a röntgenogram is absolutely indispensable. What the plate shows in a case of this sort is invaluable. And inasmuch as this is the type of case in which we hesitate to make a positive or a negative diagnosis we can readily see how great an aid the röntgenogram is in helping us make the diagnosis.

Further Studies in the Value of the Complement Fixation Test in Tuberculosis*

With observations, using the Hecht-Weinberg modification

Second Paper

By ROY UPHAM, M.D., F.A.C.S.,
Brooklyn,
Gastrcenterologist, Prospect Heights Hospital and Carson C. Peck Memorial Hospital, Brooklyn, N. Y.
and A. J. BLAIVAS, M.D.,
Brooklyn,
Pathologist, Prospect Heights Hospital and Williamsburgh Hospital. Serologist, Swedish Hospital, Brooklyn, N. Y.

Some time ago it occurred to the writers (1) to apply the modification of Hecht and Weinberg in the complement fixation test for tuberculosis. At that time we reported sixty cases, and found that the modification gave a greater percentage of positive reactions than the original technic.

It is a well known fact that the antigen is the most important factor in complement fixation work. The antigen of choice is the one that fixes complement most often in a given disease. It is the object of the writers to determine first, which is the most delicate antigen, and second, to interpret the laboratory findings.

All cases here reported were patients that consulted one of us (Upham) for gastrointestinal disturbances and tuberculosis was not suspected. Inasmuch as a Wassermann test was made on each patient as a routine, it was thought advisable to include the complement fixation test for tuberculosis, using the antigens of Petroff, Miller and Fleisher-Ives. This will, of course, account for the large percentage of negatives.

We began using this modification in conjunction with the original technic with the object of perfecting the complement fixation test for tuberculosis with the expectation that it may give as valuable and consistent information in tuberculosis as does the Wassermann test in syphilis.

The Wassermann reaction was made on each patient using both the cholesterin and ether soluble, acetone insoluble antigens. As stated above, in the complement fixation test for tuberculosis, the antigens of Petroff, Miller and Fleisher-Ives were used, and the results were estimated in terms of +, ++, +++, and ++++, but any result below +++ was considered negative. In the Hecht-Weinberg modification, any result below ++++ was considered negative.

The work was done separately, charted, and the laboratory had no information whatsoever regarding the patient. The temperature, weight, physical findings and x ray examinations were made on each patient. Each patient also received from 0.5 to 2.5 milligrams of old tuberculin and the von Pirquet test.

The table[1] shows that we have classified our cases as follows: 1. As they presented themselves. 2. Clinical tuberculosis. 3. Tuberculosis suspects. 4. Nontuberculosis. 5. Other diagnoses.

Ives and Singer (2) state that the complement fixation test recognizes only active tuberculosis. We have observed that several cases of arrested tuberculosis gave strong positive fixation tests.

While heating serum at 56° C. (inactivating) destroys any natural complement that may be present, it does not, however, destroy the natural amboceptor that may be present. Inactivating serum in the Wessermann test may destroy some of the syphilitic antibodies present and thus also render the test more liable to error. Heating serum in the complement fixation test for tuberculosis may therefore also destroy some of the tuberculous antibodies present in the serum. The fact that in the original technic the amboceptor is not destroyed, and a titrated amount of amboceptor is added to the serum regardless of the amount of natural amboceptor present, proves that an excess of amboceptor is added to the serum. This may, of course, render a negative reaction when in reality it should be positive. Bearing this fact in mind we performed the Hecht-Weinberg modification in the complement fixation test for tuberculosis.

---

*From the laboratories of the Prospect Heights Hospital, Brooklyn, N. Y.

[1] Due to lack of space we were unable to publish the table.

LABORATORY TECHNIC.

The blood was collected in the usual manner and allowed to clot. It was then centrifugalized and the serum was drawn off using a sterile pipette. The bloods were examined on the day that they were collected.

The antigens used in this series were: 1. Petroff's glycerine antigen which was furnished us by S. A. Petroff (3). 2. Miller's antigen which was generously given us by Dr. M. Kahn, of Beth Israel Hospital, New York. 3. Fleisher-Ives antigen which was furnished us by Dr. G. Ives.

Pritchard and Roderich (4) observed that guineapigs gave a strong positive reaction and upon investigation found that the sera of the guineapigs were at fault. The writers made complement fixation tests on all guineapigs and can therefore confirm the results of Pritchard and Roderich. We then discarded those animals that gave positive complement fixation tests for tuberculosis and used only those that gave clearcut negative reactions.

The guineapigs were bled from the heart and the sera of five or six guineapigs were pooled. The complement was then diluted one to ten using normal saline as diluent.

The rabbit antisheep amboceptor was prepared and titrated in the usual way. Two units were used throughout the tests.

The blood was obtained from the jugular vein of sheep into a widemouth bottle containing some sterile glass beads. It was then thoroughly shaken until completely defibrinated. The blood was then centrifugalized at about three thousand revolutions a minute about six or seven times. After the last time the supernatant fluid was tested for albumin using the nitric acid contact test. If there were any traces of albumin, it was centrifugalized again three times and the albumin repeated. A five per cent. suspension of sheep cells in normal saline was used.

In this work 0.85 per cent. salt solution was used. Care was taken that it was always sterile.

All glassware was chemically cleaned and sterilized. Although it is not absolutely necessary to have the glassware sterile, it was thought advisable to have it so throughout the serological work.

TECHNIC.

One unit of complement, two units of amboceptor and one unit of the antigen were used. One c. c. of a five per cent. suspension of sheep cells was used. After adding 0.2 c. c. of the serum, then the saline, complement and the antigens, the tubes were placed in the waterbath for one hour at 37.5° C. After this time the amboceptor and sheep corpuscles were added, the tubes were again incubated for one hour and then removed and read.

Technic for the modification.—Place 0.1 c. c. of the unheated serum into each of the twenty small test tubes which are placed in a special rack. Put one c. c. of the normal saline in tube 1: 0.9 c. c. in tube 2: 0.8 c. c. in tube 3: 0.7 c. c. in tube 4: 0.6 c. c. in tube 5: 0.5 c. c. in tube 6: 0.4 c. c. in tube 7: 0.3 c. c. in tube 8: 0.2 c. c. in tube 9: 0.1 c. c. in tube 10: 0.2 c. c. in tube 11: 0.15 c. c. in tube 12: 0.1 c. c. in tube 13: 0.2 c. c. in tube 14: 0.15 c. c. in tube 15: 0.1 c. c. in tube 16: 0.2 c. c. in tube 17: 0.15 c. c. in tube 18: 0.1 c. c. in tube 19: and 0.3 c. c. in tube 20.

The first ten tubes are used to determine the hemolytic index of the blood under examination. In other words, the first ten tubes are used to determine the amount of natural complement and amboceptor in the suspected serum. In tubes 11 to 19 inclusive, the actual test is carried out. Tube 20 is the serum control tube.

Now add 0.1 c. c. of a five per cent. suspension of sheep cells to tube 1: 0.2 c. c. to tube 2: 0.3 c. c. to tube 3: 0.4 c. c. to tube 4: 0.5 c. c. to tube 5: 0.6 c. c. to tube 6: 0.7 c. c. to tube 7: 0.8 c. c. to tube 8: 0.9 c. c. to tube 9: and one c. c. to tube 10.

Dilute the titrated antigens used in the original technic with equal quantities of normal salt solution.

Place 0.1 c. c. of the diluted Petroff's antigen into tube 11: 0.15 c. c. into tube 12: and 0.2 c. c. into tube 13.

Place 0.1 c. c. of the diluted Miller's antigen into tube 14: 0.15 c. c. tube 15: and 0.2 c. c. tube 16.

Place 0.1 c. c. of the diluted Fleisher-Ives antigen into tube 17: 0.15 c. c. into tube 18: and 0.2 c. c. into tube 19.

These nine tubes (11, 12, 13, 14, 15, 16, 17, 18, and 19) are the tubes in which the final reading are made and for that reason the antigen is added to them. Tube 20 being the serum control tube, receives no antigen. The tubes are now well shaken and placed into the waterbath for one hour at 37.5° C. At the end of this time the rack is removed from the waterbath and the last tube which shows complete hemolysis is the hemolytic index. For example, if tube 7 is the last where complete hemolysis occurs, the hemolytic index is 7. This means that 0.1 c .c. of serum will hemolyze 0.7 c. c. of a five per cent. suspension of sheep corpuscles.

In order to determine the quantity of sheep cells to put into 11 to 20, it has been the custom to use the same table as used in performing the Hecht-Weinberg test for syphilis. If the hemolytic index is from 1 to 4, add 0.1 c. c. of sheep cells to tubes 11 to 20 inclusive; 5 to 7, add 0.15 c. c. of sheep cells to tubes 11 to 20 inclusive; 8 to 10, add 0.2 c. c. of sheep cells to tubes 11 to 20 inclusive.

After the addition of the sheep cells to tubes 11, 12, 13, 14, 15, 16, 17, 18, 19, and 20 the contents of the tubes are well shaken and again placed in the waterbath for one hour at 37.5° C. This rack is then removed and the results read just as in the Wassermann test.

We wish to call attention here to a modification of the Hecht-Weinberg test.

From the above table it will be observed that if a serum has a hemolytic index of 1, it will receive the same amount of sheep corpuscles in the test as the serum that has an index of 4. This, scientifically, did not seem correct to the writers. We then began trying to solve this difficulty and came to the following conclusions, which were worked out on a practical basis and proved to be more accurate and scientific than the table given by Gradwohl.

After the hemolytic index has been determined, exactly twenty-five c. c. of the sheep corpuscles are thoroughly mixed and added to twenty-five c. c. of sterile saline. This solution was termed by one of us (Blaivas) the socalled index solution.

Then, if the hemolytic index is 5, five c. c. of this index solution is added to tubes 11 to 20 inclusive. If the hemolytic index is 1, then one c. c. of the index solution is added, etc. This technic has also been employed in the Hecht-Weinberg modification of the Wassermann test in syphilis and found to be superior to the Gradwohl table. A further report of this technic will be reported later.

From our table we observed that there were thirty positive fixation tests in the original test and fifty-eight positive fixation tests in the modification. The following results were obtained:

Petroff's antigen	positive 58
Miller's antigen	positive 39
Fleisher-Ives' antigen	positive 46

In no instance was there a positive reaction with Miller's or Fleisher-Ives's antigens, and a negative reaction with Petroff's antigen, but there were many positive reactions with Petroff's antigen, and a negative reaction with Miller's antigen, Fleisher-Ives's antigen or with both.

We have therefore decided that in our future complement fixation work in tuberculosis, we will abandon Miller's and Fleisher-Ives's antigens and use only Petroff's antigen.

CONCLUSIONS.

We have reported the results of the complement fixation test in tuberculosis in 254 cases.

In twenty-one of these cases a positive diagnosis of tuberculosis was made without using the results of the blood tests. Twenty-three of these cases were tubercular suspects and six were questionable cases of tuberculosis.

Our results with the complement fixation tests may be summarized as follows:

Positive reactions in the original test	30
Positive reactions in the modification	58
Positive Wassermann tests	20
Positive Hecht-Weinberg tests	31

There were thirteen bloods that had no hemolytic index, and in those cases the modification could not be used.

Positive Von Pirquet Tests	92
Diagnosis of tuberculosis with positive reactions in original test	11
Diagnosis of tuberculosis with positive reactions in modification	17
Questionable cases of tuberculosis with positive reactions in original test	4
Questionable cases of tuberculosis with positive reactions in the modification	8
Tuberculosis suspects with positive reactions in the original test	6
Tuberculosis suspects with positive reactions in the modification	12
Diagnosis of tuberculosis with negative reactions in the original test	10
Diagnosis of tuberculosis with negative reactions in the modification	6
Diagnosis other than tuberculosis with positive reactions in the original test	7
Diagnosis other than tuberculosis with positive reactions in the modification	23
Diagnosis not made, with positive reaction in the original test	1
Diagnosis not made, with positive reactions in the modification	2
X ray of chest positive, with positive reactions in the original test	3
X ray of chest positive, with positive reactions in the modification	5
X ray of chest positive, with negative reactions in the original test	5
X ray of chest positive, with negative reactions in the modification	1

We have shown that twelve tuberculosis suspects gave positive reactions, seventeen cases of tuberculosis gave positive reactions and five cases with positive x ray findings gave positive reactions, whereas only six cases of tuberculosis gave negative reactions.

COMPARATIVE VALUE OF TESTS.

From our results with both tests it will be noted that the modification of the complement fixation test in tuberculosis is much more sensitive than the original technic. We always get a greater percentage of positives in the modification and in known cases of tuberculosis the modification gave almost fifty per cent. more positive results than did the original test. In known cases of tuberculosis there were forty per cent. more negatives with the original test than with the modification. We will therefore continue using the modification of the complement fixation test for tuberculosis in conjunction with the original test.

We also wish to state that in our experience there seems to be no crossfixation in syphilis.

From the summary, we conclude that we have obtained some valuable information from the complement fixation in tuberculosis. Not only is it an aid to diagnosis, but where there is a positive result, the clinician should go further into the case using every known method to establish an accurate diagnosis. If it has done no more than make the physician more careful, more observing, and more accurate in diagnosis, the test has achieved a definite place in medicine if used properly.

We wish to express our thanks to Dr. J. L. Sengstack for his valuable aid in this work.

Tuberculosis and Poison Gas*

By A. P. FRANCINE, A.M., M.D.,
Harrisburg, Pa.,
Lieutenant Colonel Medical Reserve Corps; Chief of Division of Tuberculosis, Pennsylvania State Department of Health.

To be understood I must first give you a picture of poison gas as it was during the last four months of the war following the formation of the First American Army. Not as it is popularly imagined to be, or may have been. The experience on which my opinions are based consists of four months' service as consultant in gas to the Fourth Army Corps in the St. Mihiel and Argonne sectors, six weeks of which was spent as resident Physician-in-Chief to the great gas hospital at Toul. It therefore concerns only the effect of gas as I saw it on American troops at a time when gas discipline was generally good and our type of gas mask effective. The effect of the only gas which I will consider is mustard gas, because it was almost exclusively used and had become recognized as the most effective of all battle gasses in producing casualties.

It should be understood that socalled mustard gas is not what many people would consider a gas at all, but is a heavy oil thrown in shells. Great extent of terraine can be contaminated for long periods of time, as long as ten days to two weeks, particularly in damp, wet, low lying fields or woods. It volatilizes with difficulty and only under warm sunshine. When it volatilizes it is detectable by odor. Any troops going into such areas, or sleeping there, are burned (gassed). It is usually not inhaled at all. Its action is escharotic, like ivy poisoning, if you will. Burns take some time to appear; often twenty-four hours.

So that when I think of the hundreds of men littered into the hospital every night or so, I do not picture men who were coughing, choking or gasping for breath, for they were not; but of cold, exhausted, quiet men, burned more or less severely about the eyes and body. Approximately eighty per cent. of our cases were suffering from mustard gas. Seventy-five per cent. of these were not severely gassed, and of this number twenty per cent. were probably not gassed at all but were victims of exhaustion, shell-fume, and other conditions.[1]

Other types of gas like phosgene and chlorine are vastly more deadly but are only effective in such high concentrations; hence in such a restricted area as to be very ineffective as compared with mustard gas. It is vastly more important to put two hundred men permanently out of the lines (only slightly injured though they may be), than to kill five men outright.

That is one reason why the later use of gas was infinitely more humane than shot and shell. In only about twenty per cent. of admission was the condition severe enough to confine the men to bed for more than forty-eight hours.

DIAGNOSIS.

Diagnosis was usually evident on admission, though 191 cases were classified (erroneously I believe) as due to phosgene. None of these patients showed pulmonary complications, except a few râles which soon disappeared. None of these patients died.

TREATMENT.

Treatment was simple, carried on by medical officers, nurses, orderlies and convalescent comrades. I was particularly interested in studying the chests of these men and went over hundreds of them with care. In the majority there were no clinical findings whatever. In some there were râles; apparently from the history, the result of an already existing bronchitis. These often cleared up after a day or two of rest in the hospital. The same is true of coryza. In a few patients whose lungs were clear on admission there developed influenza or bronchitis, which appeared possibly due to cross infection, so beds were cubicled to prevent this.

Except in relatively few cases I could attribute no possible relationship, and at no time anything of a permanently damaging nature to the lungs from gas. In other words they had not inhaled the fumes, or very slightly. There was little more in these chests than one would encounter in any general medical ward, and not as much as one would find in a clinic devoted to diseases of the chest. There was no active tuberculosis noted. No tubercle bacilli were found in those who had expectoration, not even in the few who had râles and for some days blood streaked sputum.

CAUSE OF DEATH.

The percentage of deaths in the gas hospital was 1.98 per cent. All the deaths were from mustard gas. This percentage again goes to show that the mortality and effects of gas have been, as was to be expected, greatly exaggerated and misunderstood in the minds of laymen, soldiers, and doctors, who did not study it closely and among large groups. This is to be understood as relating to the later months of the war, when gas defense had become well developed.

A few died directly from prolonged inhalation of the gas, or in great concentration. At autopsy the bronchial tubes were found seared as with a red hot iron and the lungs were bloody sponges. It might be argued that sufficient time had not elapsed for the lighting up of a tuberculous process. However, death occurred among a number of men who were badly burned about the body who had inhaled gas and who had been in the hospital from five to seven weeks. They were sick, weak, but improving; and each patient died from an intercurrent infection such as, myocardial insufficiency (asthenia), nephritis, or from acute influenza (bronchopneumonia). No evidence of reactivation of existing tuberculous lesions was found in these cases at autopsy.

---

* Read before the National Tuberculosis Association, Washington, D. C., May 6, 1922. My paper being limited to ten minutes must necessarily be brief, and to an extent incomplete.

[1] Report for hospital kindly furnished by Major A. G. Love, M. C., U. S. A. Exact statistics are not available for a number of reasons, i.e., the uncertain hour and hurried nature of admissions and evacuations, lack of personnel, etc.

The skin burns healed rapidly and these men were evacuated to base hospitals usually in from four to seven days. Their chests were carefully examined before evacuation and their lungs were clear, or there was only a mild bronchitis, in practically all instances. Some who were slightly gassed and in good physical shape were returned after a few days' rest to their organizations in the line.

MENTAL SHOCK.

I believe, however, that there was a certain mental shock from having experienced in even a slight degree, a touch so to speak, of this little known and dreaded gas. This I know to have been the case in the production of aphonia in certain cases, purely neurotic in origin; which has yielded to appropriate treatment. There may have been other resultant effects with which I am not familiar, but certainly none of a pulmonary character. It seems, however, true that a man who has once been gassed has come to attribute (whether sincerely, or through ignorance, or not) any illness, from pain in the chest, shortness of breath, acute bronchitis, or tuberculosis, to his gassing.

A number of such cases which I have personally examined were found never to have been gassed at all. In some instances they were taken for a night to one of the advanced triages, or field gas hospitals for observation, and returned to the lines without evacuation. They had never passed through the evacuation gas hospital of the justice group (Toul) as they would have had to do were they really gassed at the time they specified.

That gas, as I saw it, from the point of view of one who had had considerable preliminary experience in conditions of the chest, could leave any damaging effects, not only on the lungs, but elsewhere, is inconceivable, as the injuries were usually so slight. I have been informed informally, however, that the Veterans' Bureau is paying for disability indirectly attributable to gas about twenty per cent. of its disbursements.

I have only attempted to give you my personal impressions mellowed by medical experience in civil life. Brigadier-General Amos A. Fries, Chief of the Chemical Warfare Service, has dealt with this subject in a masterly and interesting way, as has Colonel H. L. Gilchrist and Colonel James Robb Church. Let me quote from a paper by General Fries:

"According to the report of the Surgeon General, United States Army, for 1920, 258,338 men were injured during the war. Of these 34,249 died on the field of battle and 13,691 died in hospitals. There were admitted to the hospitals (this does not include marines) 224,089. Of this number, 70,552, or 27.3 per cent., were suffering from gas alone. Of the 70,552 gas cases, only 1,221 died. Of the 153,537 admitted to the hospitals suffering from bullets, high explosives, and other methods of war except gas, 12,470 died. Of those killed on the field of battle, we know that very few—probably under 200—were from gas, since concentrations of gas sufficient to kill within say twelve hours were seldom obtained. If we assume that 200 died from gas on the field of battle, the total deaths from gas would be 1,441 out of 70,752, or less than two per cent. In like manner, of the 187,586 injured by bullets, high explosives and similar methods, 46,449, or more than twenty-four per cent., died. Thus it is evident that the man who was injured by gas alone on the field of battle had twelve times as many chances for recovery as the man wounded with bullets and high explosives."

"Other comparisons are still more striking. On page 21 of that report we are told that eighty-six men were totally blinded in the war, forty-four were partially blinded in both eyes, and 644 were blinded in one eye. These include eyes destroyed or those in which the sight was lost. Of the gassed patients, it is stated that four were blinded in both eyes and twenty-five in one eye, a total of twenty-nine. These twenty-nine were 3.85 per cent. of all those suffering blindness in one or both eyes. In other words, bullets, high explosives, and other methods of warfare than gas were responsible for twenty-five times as many blinded as were gassed."

CONCLUSIONS.

Concluding, from my experience during the last four months of the war, when there was intense use of gas:

1. The terrible impression people have of gas arises from its early, tragic, inhuman, and indefensible use against troops, surprised and defenseless before this untried but potent offensive weapon. This contrary to the Hague Convention.
2. People generally, including the rank and file of Army men, have a much distorted mental picture of its effects, and begin by thinking of it as of the nature of deadly fumes. Generally speaking it is nothing of the sort. The effects of gassing (mustard) are in the majority of cases superficial eye and body burns.
3. Mustard gas is the most effective of all battle gases in being the greatest casualty producer, and hence was by far the most widely used. It is rarely inhaled. It is a burn.
4. The percentage of deaths from gas was both absolutely and relatively extremely low; and of permanent disability (blindness) negligible.
5. Poison gas put more men out of action with less hurt to the individual than any branch of the service.
6. Following the perfection of methods of defense against it, it became many times more humane than shot and shell as proven statistically above.
7. Anyone who saw closely the use and effect of gas would far rather be exposed to a gas attack than take a chance with a half inch of red hot flying steel.
8. One might even be excused for characterizinz it as benign to the extent, that it put so many of our men (nearly seventy thousand) out of the war with usually slight and temporary injuries, who would otherwise have continued to be exposed to the damaging effects, severity, and cruelty of gun fire. Of course, it may be objected that the lines were kept filled by replacements, and while measurably true, yet gas at least saved these particular gassed men.
9. It would appear incapable of leaving any pathological aftereffects. It is inconceivable that gas (as it is, and not what so many people consider it to be, or what it may have been) could reactivate tuberculosis, and available statistics and majority expert opinion go to prove that it does not do so. This view is endorsed by French, British, and other authorities.

Shall We Tell Our Tuberculous Patients the Truth?*

By ARNOLD MINNIG, M.D.,
Denver, Colo.

On the face of it the question seems silly, but practically it is a question which is constantly proposed for solution and one which the physician must decide with nothing but his own knowledge and experience to guide him. Shall we tell the hopeless third stage patient who is bravely battling for his life that his fighting is all in vain, that he has no chance, and take away hope, the only thing that is left him? Shall we tell the nervous, emotional, self-centered woman—or man—who is in the incipient stage that she has tuberculosis, and let a disordered, egoistic imagination frighten her—or him—into a more advanced stage of the disease? On the other hand, shall we let the patient in an advanced condition do unwise things for want of complete knowledge of his condition, or the foolish woman—or man—forego the benefit that intelligent guidance could give? It seems such a simple question—shall we or shall we not tell the truth?—but like many other apparently simple problems, it is exceedingly difficult to solve.

Let us examine some of the principal reasons for telling or withholding the truth. Innate honesty and care for one's reputation naturally prompt one to speak the truth, but even here the welfare of the patient must be the first consideration. A reputation for truthfulness is the greatest possible help in winning and retaining the confidence of patients. But the most important reasons for frankness are—to enlist the intelligent cooperation of the patient, and to keep him from doing harmful things. Many patients will not observe proper precautions until they are thoroughly frightened, but this is a healthy scare and rarely does harm.

The reasons against telling the patient of his true condition are, first, the fear that the dread word tuberculosis inspires, and unfortunately this is not a healthy scare; secondly, the danger of discouraging the patient, taking away his greatest comfort and most powerful weapon—hope. Even if the case is hopeless, surely it is better to die fighting than to give up in helpless despair.

The problem is purely a psychological one. It has disturbed me for years, and I do not feel because I am talking about it that I know the solution. It is also an individual problem, that is, each case must be treated individually according to the mental make-up of the patient. We adapt the dose of medicine to the physical size and weight of the patient, we must adapt the mental treatment to his mental and moral size and weight. The big, flabby, two hundred pound man who collapses at the mention of tuberculosis must be treated like the overgrown baby that he is, and given his pills thickly sugar coated and in as small doses as possible, while the quiet, self-contained person who can face facts squarely can be told the plain truth without fear of untoward consequences. This type will appreciate the frankness and honesty of the physician, while reticence would arouse suspicion and mistrust. These are only two of innumerable types and each one must be treated according to his kind. A thorough working knowledge of psychology is essential to the success of a physician.

One thing that physicians often fail to realize is the belief of a not inconsiderable part of the public in the incurability of tuberculosis. It is not many years since the medical world held the belief that tuberculosis was incurable. We now know that it is one of the most curable of diseases, that most people at some time in their lives have had some form of it. But knowledge percolates slowly from the classes to the masses, so a large number of people still believe that the disease is incurable. This impression should be removed not only from the minds of patients but of the public as well. This would remove much of the fear, and greatly simplify the work of the physician.

So what is the solution of our problem? Shall we tell patients the truth? Decidedly, yes! Why? Tuberculosis is a disease with a marked tendency to recovery. The whole Rocky Mountain region is here as evidence of its curability. We can therefore speak encouragingly as to the prognosis in the majority of cases. People prefer encouragement to discouragement.

Furthermore, we are not always sure of our prognosis. Time and again all of us have predicted an early end of patients who have surprised us by getting well or at least have lived much longer than we expected. This is the exception rather than the rule, but it does occur.

If we eliminate hope from our treatment we have taken away one of our strongest natural weapons of defense. On the other hand, in order properly to defend themselves patients must know the truth. How can a patient intelligently combat a trouble without knowing what it is?

When one sees year after year the mistakes patients make and how they might be avoided, and finally can pick out, as most specialists in lung diseases can, the patients who are going to get well and those who are going to die, the need for more forcible arguments and a more convincing exposition of the case, becomes tragically greater. We are not always able positively to say that one case will live and the other will die, but as a rule, we can.

I know of no more impressive place to see the tragedy of the errors of the consumptive than in the free tuberculosis dispensaries.

We see them come from the East penniless or nearly so. Often as soon as they arrive they feel better, due to the bracing, exhilarating effect of our altitude and wonderful climate. It may be that in the East the patient was unable to work—in fact, was a bed patient, but soon after coming West he feels so much better he thinks he can climb the mountains, which he often does with disastrous results.

As I so often tell patients, if we had an index such as breaking a leg the minute tuberculous activity starts, the patient might pay attention to the seriousness of his case. Most people not breaking their legs at this particular time we do not have this index. In fact, we have no index except the physician's opinion, and that opinion may be ever so good, yet the patient when he first hears the news that he has tuberculosis is not satisfied and often does not believe it. He then goes to another doctor, several it may be. I recently saw a patient with advanced pulmonary trouble who was told by seven doctors that he had lung trouble, so he went to an eighth who told him he had none. He stayed with the eighth longer than with any of the others. Patients always insist that they want to know the truth of their condition, but they are often unwilling to accept the verdict.

---

*Read before the Medical Society of City and County of Denver, May 2, 1922.

I remember one case which was especially impressive. The patient was a woman of thirty-two. She had been a business woman before and after she was married. She seemed the wiry type, but at last she became so exhausted at her work that she had to give it up. She came to me with the admonition that she did not want to be examined unless I told her the truth. I examined her and proceeded to tell her my findings. I told her the truth. I told her that I thought she had had tuberculosis for some time. However, there was no sputum and the x ray was negative. At this examination there was no rise in temperature. What was the result? I did not see the patient again for a year. During the interval she had seen several doctors, who assured her after repeated examinations that her lungs were all right. Some time after I examined her she had a hemorrhage. The doctor and patient were finally convinced. A year later she returned to me. She now thinks I know my business and even tell the truth.

About two years ago a patient from the East came to the tuberculosis dispensary. He was not able to work back there, but felt better as soon as he came here. We told him he had advanced tuberculosis and should not work. Forthwith he started to work and worked fairly regularly for a year. He then came again to us. Examination revealed hopeless progress of the disease yet the patient complained of nothing except some shortness of breath. Telling the truth does not always produce the desired effect.

Another instance is rather typical of many others. A man and his family came here from the East. I was called the next day. They wanted to know the truth and what my advice was as to treatment. I told the wife her husband was going to die soon and that they had better go back home as soon as possible. I was discharged. The patient died in ten days.

The thing does not always work so badly for the doctor. I have at present a patient who has been going to a quack woman physician who said she could be cured in ninety days for two hundred dollars and that she would guarantee the cure. This was a third stage case. At the end of the ninety days the patient was assured she was well. Not recognizing any of the symptoms of wellbeing, strange as it may seem, she became suspicious and did not enjoy the sensation of being stung. She heard from a neighbor that I had the reputation of telling the truth, so she came to me and has stuck, although she was hopeless when she came.

It does seem discouraging to see on all sides quacks and charlatans assuring patients that they can cure tuberculosis and fraudulently extracting all their money. A case I had a number of years ago will illustrate my point.

A man with his wife and children came here from Minnesota. During the influenza epidemic they were all ill except the man for whose health they came. He nursed them all. On examining the man I found a large cavity in one apex. He was a well advanced third stage case. The money was beginning to run out and they moved to the suburbs. I took care of this man for about two or three years for nothing and about a month of this time I put him into the County Hospital on account of a hemorrhage. They represented to me that the sole support of the family was the mother, who was working at a local dry goods store at fifteen dollars per week. I called on the city charities and the visiting nurses' association. For several years we all worked together on the man and the family. Recently I saw the man on the street hobbling along with a cane, almost unable to walk. He told me he had been up to see a woman doctor who was giving him electric treatments and was curing him.

My plan nowadays is as good as any I know. People say they want to know the truth, but do they? I feel that the honorable medical man must direct these unfortunates in the right way. The first essential is to gain the patient's confidence. This is not usually possible at one visit, but it comes after a while. Then, pointing out the hopeful prognosis of many of these cases and how it is the tendency of the disease to get well, we must in as attractive form as possible according to the case, and as fast as possible point out with firmness the reality, that it takes many months or a year or two, it may be, for the patient to get well and that it is his duty to make a fight. There will not be much trouble with the patient who cooperates and does well, but with him who does not get along it is indeed a hard job to keep driving old man gloom from the door.

The issue at stake is a human life. Patients are not mental defectives and should not so be treated. In most cases, therefore, we can conscientiously give them encouragement. That is what they want. Therefore it is acceptable. On the other hand we must also tell them the facts as we know them. Indeed, it would be a crime for the medical man not to do so. It is only after the patient learns the unvarnished truth that the physician can enlist his aid and cooperation in the business of getting well.

In conclusion, I should say that the medical man who does not tell his patients the truth is guilty of a crime just as truly as any criminal is guilty. The doctor who puts his truth in as attractive form as possible is doing this class of patients the greatest amount of benefit. To do this he must first gain the patient's confidence, then slowly but surely put him face to face with the truth. If he then leaves us we have done our part. We have upheld the honor of the profession if we have done the very best as we see it. We shall have done something worth while, and with time will be rewarded by a profitable following and, best of all, by a clear conscience.

Abscesses Descending from the Upper Air Passages*

By OTTO GLOGAU, M.D.,
New York,
Honorary Member Austrian Otological Society.

In the *Festschrift* to Prof. M. Hajek's Sixtieth Anniversary (November, 1921) and in the July, 1922, issue of the *Laryngoscope,* I have in detail described the typical external operation for the abscesses descending from the upper air passages. Through the courtesy of my esteemed teacher, Prof. M. Hajek, I worked last summer at his clinic as aspirant and had thus an opportunity to evolve this method, basing it upon studies made on the cadaver, on the observation of cases operated upon during my stay at the clinic and upon the perusal of the records.

I will report three cases where I have used this method, since my return to this country, and will point to the one case previously operated upon in a similar way. The abscesses descend from the upper air passages and the base of the tongue, that lead to phlegmon of the neck and to affections of the mediastinum, originate mainly from angina of the faucial tonsils, tonsillar and peritonsillar abscess, following tonsillectomies, following phlegmon and erysipelas of the pharynx, following laryngeal phlegmon, following foreign bodies, as secondary descending abscesses, which originate after lues, tumors, infections of the teeth, the jaw, the sinuses and other affections of the upper air passages and their adnexa.

The operative method recognized by me as a typical one bases upon the topographical and anatomical conditions, as they decide in every case the path along which the abscess may descend. It is evident that all inflammations originating in the neighborhood of the pharynx, the tonsils, the base of the tongue and the laryngeal region descend into the loose connective tissue interstices of the neck that surround the pharynx. Consequently, however different the places of origin may be, all these descending abscesses act in their further course analogously and furthermore may be reached by one and the same method.

To illustrate the operative procedure I have had made three pictures that demonstrate the different steps of the operation. The first picture shows the skin incision that reaches alongside the anterior margin of the sternocleidomastoid from the level of the mandibular angle to the jugular fossa.

The second picture illustrates the exposure of the collar mediastinum. From the lower part of the incision, through the superficial fascia of the neck, the vascular sheath is reached by blunt dissection, and the anterior margin of the vessels is located without further dissecting the vessels. Then the omohyoideus is divided. Following the course of the vessels, the anterior collar mediastinum is exposed and sealed with a drain of iodoform gauze tampon, as is also seen in the picture. The thyroid gland is now moved forward and towards the median line without injuring its capsule.

By lifting the thyroid gland, the posterior collar mediastinum is exposed, and simultaneously the wall of the esophagus and the vertebral column appear.

The operative procedure up to this point is carried out both in the presence of a healthy and of a diseased mediastinum; in the first case to seal the healthy mediastinum by iodoform gauze tampon against the possible progressive tendency of the pus (prophylactic mediastinotomy of Marschick), and the second case to drain it.

The third picture demonstrates the operation proper, which can only be attempted after the sealing or draining of both collar mediastinal spaces. At the upper part of the incision, along the sternocleidomastoid, one progresses towards the depth, guided by the inner margin of the vascular sheath. This picture represents a certain individual instance of the typical operation, dealing with the drainage of abscesses descending from the lateral pharyngeal wall, especially the tonsils. The lower belly of the *digastric* serves as a topographic line of orientation. Within the vascular sheath the common carotoid artery and its division into the external and internal branches may be recognized. Caudally from the digastric the hypoglossus nerve is located. In the space beneath the digastric as is indicated in the picture, a dressing forceps is introduced into the direction of the mandibular angle and is pushed upward into the parapharyngeal space, beneath the mucous membrane of the pharynx, and spread open into different directions (subbiventral method). If we have to deal with the opening and drainage of abscesses localized elsewhere within the upper air passages or at the base of the tongue we must, in every individual case, differ from the described type of operative procedure, according to the exactly localized place or origin of the abscess.

By previous pharyngoscopic examination we determine, as well as possible, the location of the abscess and the level at which it originated, and which special way the suppurative process took in the course of its progress.

The operative method described above was successfully applied in the following three cases:

Case I.—Ch. T., eleven months of age, was referred to me on February 2, 1921, by Dr. Charles F. Fisher, of Brooklyn. The child was born in the United States. The parents were Russian and had always been in excellent health. The child was breast fed and got its first teeth at six and a half months. The present sickness was the first one the baby suffered from. About three weeks before, the baby cried all night, the mother gave it castor oil and a soap and water enema, without avail. The next day a physician was called who found a temperature of 104° and rapid pulse. He also noticed a swelling on the left side of the neck. The doctor suspected peritonsillitis and prescribed a mouth wash and internal medicine. As the child's condition grew worse, an ear specialist was called who opened both drum membranes, an x ray picture was taken but proved to be negative. The child's condition grew constantly worse. A specialist was then consulted who thought that an abscess was forming somewhere but could not locate it. Meanwhile the child started to choke, especially at night, and would not take the bottle, and if forced to do so would vomit immediately. Another baby specialist was consulted who stated that the stomach was out of order and prescribed a special diet. The baby grew weaker, the breathing became more obstructed. The temperature showed a daily range from around 99° to 104°. During the last few days the child had chills. Dr. Charles F. Fisher, who saw the child in the morning, suspected a deep abscess in the neck and referred the patient to me.

---

*Read before the Meeting of the American Academy of Otolaryngology, Minneapolis, September 21, 1922.

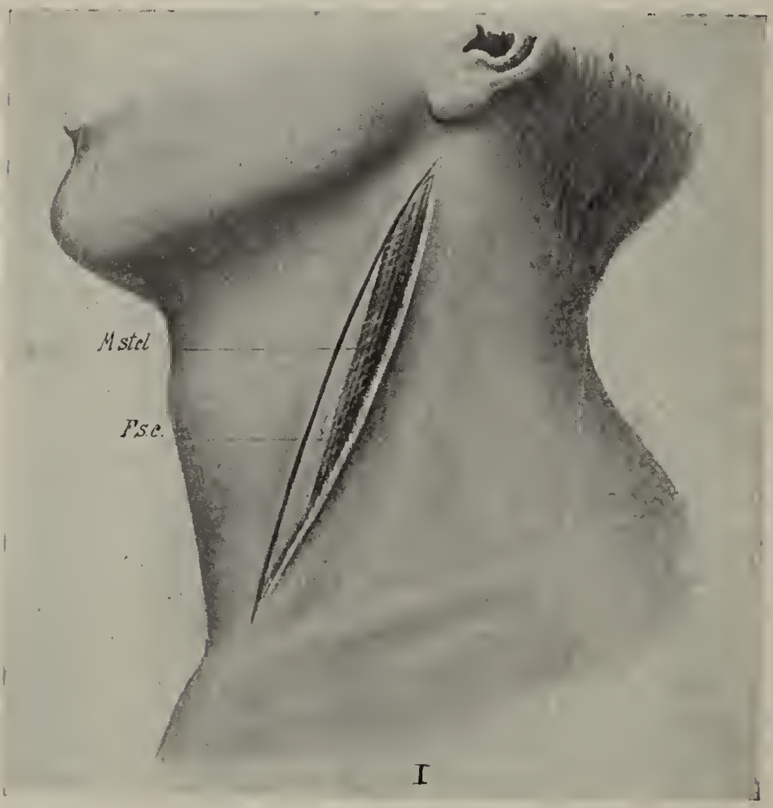

Fig. 1.—Showing skin incision.

The baby was well developed, extremely pale and apparently very ill. It was gasping for air and slightly cyanotic. When given the bottle, it vomited immediately, temperature 104°, pulse 100. Local examination revealed no apparent pathological change within the throat, with the exception of a marked redness at the base of the tongue, at the region of the vallecula. Digital examination revealed a fluctuating swelling on the posterior wall of the esophagus, starting at the level of the arytenoid cartilage and apparently reaching far downward. On the outside there was a dense infiltration noticeable on the left side, at the anterior margin of the sternocleidomastoid, starting from the mandibular angle and reaching down to the larynx. The swelling was slightly discolored and sensitive to pressure. There was a special sensitiveness to pressure present at the region of the jugular fossa. Heart and lungs were apparently normal.

A diagnosis of descending retroesophageal abscess with phlegmon of the neck and threatening mediastinitis was made. Immediate operation was advised. The operation was performed at the Lane Sanatorium, February 2, 1922, at 1:30 p. m. Dr. Levengood assisted, Dr. Lane was the anesthetist. Superficial ether narcosis was given.

The incision was made alongside the anterior margin of the sternocleidomastoid muscle, from the mandibular angle to the jugular fossa, ligation of the superficial vessels, blunt dissection made alongside the anterior margin of the muscle to the depth of the vascular sheath, whose anterior margin is located, without opening the sheath proper. At the lower aspect of the wound the omohyoideus was severed. Following the inner margin of the vascular sheath downward, the anterior mediastinum was exposed. It was found normal and sealed with iodoform gauze tampons. The thyroid gland was then pushed forward and towards the median line, without injuring its capsule. By lifting the thyroid, the posterior mediastinum was exposed. As it was found to be in a healthy condition, it was sealed with an iodoform gauze tampon. Having protected both the anterior and posterior mediastinum (prophylactic mediastinotomy of Marschick) the abscess cavity was searched for at the upper aspect of the wound. Here, too, the inner margin of the vascular sheath was located; but the tissues were hard and indurated, and it was impossible to continue working towards the depth by means of blunt dissection. It looked rather daring and desperate to use a knife so close to the carotid artery. But the preceding pharyngoscopic examination pointed the way. At the level of the cricoid cartilage, the indurated mass was incised right close to the anterior margin of the vascular sheath, about one millimetre from the carotid artery. The larynx was grasped with the left hand and pulled outward. When the incision had been carried about one cm. further towards the depth, there gushed forward under high pressure about five ounces of creamy, foul smelling pus. Starting from this point, the indurated mass of tissue was then opened further upward and downward by means of the finger. Digital examination of the abscess cavity showed it to be about two and a half cm. in width and eight cm. in length. The vertebral column could be clearly felt beneath its fascia, but no roughness pointing to bone affection could be noticed.

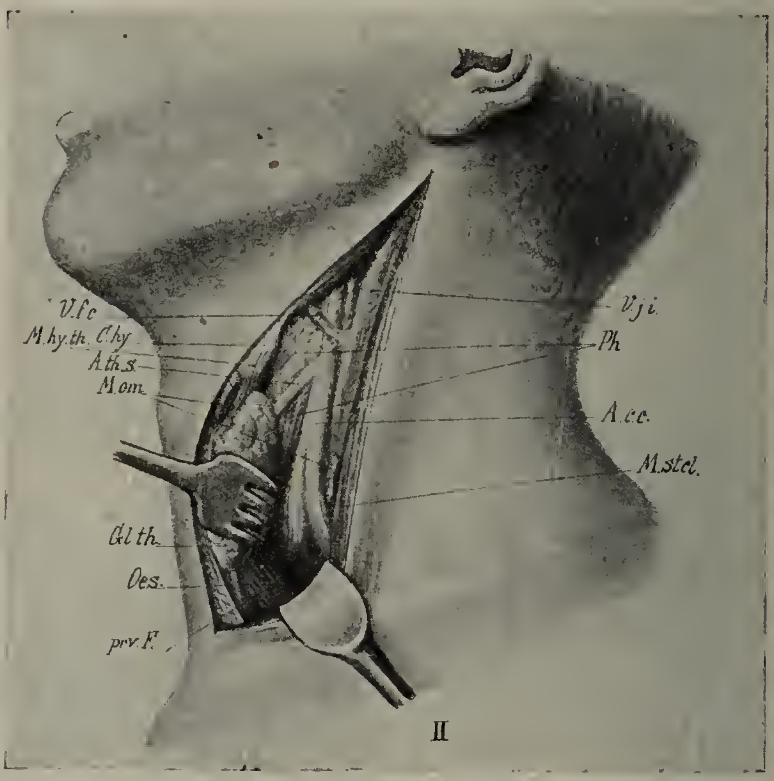

Fig. 2.—Illustrating the exposure of the collar Mediastium.

Two cigarette drains were introduced into the abscess cavity and the wound left open. Immediately after the operation the child's condition showed a remarkable change. The same evening it sat up in bed, breathing normally, it asked for the bottle of milk which it emptied without difficulty. The temperature dropped within a few hours and the pulse improved with it. The night after the operation the child slept quietly. The outside dressing was changed every day. On the fourth day the mediastinal tampons were removed and on the fifth day the two cigarette drains, as there was no more discharge whatsoever present. With the removal of the drain a slight irritative cough stopped, which was due to the pressure of the drain towards the larynx. On the sixth day the child was dismissed from the sanatorium as cured. After one more week the wound had entirely healed by secondary intention.

Case II.—Represented a similar condition in an adult. S. H., thirty years old, was referred to me on April 11, 1922, by Dr. Mark I. Schoenberg, of New York City. Twelve days previously the patient caught a cold and immediately noticed a swelling on the left side of the neck. This swelling, however, disappeared, but came back four days later. Since that time the patient has felt a choking sensation, had pain in swallowing and experienced shooting pains toward the head, back and arms, and could not open his mouth very well. He was gasping for air. He had a subicteric discoloration and was apparently sick.

There was no apparent inflammation present at the tonsils, base of the tongue, or pharynx. Laryngoscopic examination revealed, at the level of the posterior laryngeal wall, at the left side a forward bulging of the esophageal mocous membrane. There was severe pressure pain along side of the anterior margin of the left sternocleidomastoid at the level of the thyroid cartilage. At the right side the same pain was elicited but only on deeper pressure. The patient held his head stiff and inclined to the left side. There was a diffuse infiltration present in front of the left sternocleidomastoid from the mandibular angle to the larynx. Swallowing was extremely difficult. The patient was cyanotic. There was severe tenderness to pressure present in the jugular fossa.

A diagnosis was made of a descending retroesophageal abscess with phelgmon of the neck and threatening mediastinitis. The patient was operated upon at the Community Hospital, Dr. Hoiland and Dr. Grove assisting, anesthetist Dr. Hraba. The operation lasted from eight to nine p. m. Superficial ether narcosis was given. The incision was made along side the anterior margin of the sternocleidomastoid from the mandibular angle to the jugular fossa. By blunt dissection, especially with the finger, at the lower margin of the wound, the anterior mediastinum was opened and sealed with iodoform gauze tampons. The thyroid gland was then pushed forward and the posterior mediastinum exposed and sealed in the same way. At the level of the cricoid cartilage a solid mass of indurated tissue was found in front of the vascular sheath together with enlarged and degenerated glands. First by blunt, and then by sharp dissection, it was worked towards the depth. In front of the carotid artery, without opening the vascular sheath, the retroesophageal tissue was reached and about six ounces of foul, yellowish creamy pus evacuated. Digital exploration showed a large cavity between the fascia of the vertebral column and the fascia of the esophagus, reaching downward about five cm. and encroaching upon the other side. The wound was left open except for two stitches at the ends. A wet dressing was applied.

Due to the bad breathing of the patient I was ready to tracheotomize him at any moment. The anesthetist remarked that the instant the pus was evacuated the patient's color immediately changed to normal and his breathing improved remarkably. The narcosis was a superficial one and the patient soon after the operation cried out, "Oh, I feel so much better." The next day he smoked cigarettes and ate three hearty meals; he did not complain of pain any more. The outside dressing was changed every day. The mediastinal gauze strips were removed on the fourth day, the cigarette drains of the abscess cavity on the sixth day. On the eighth day after the operation the entire wound, which had been left open, was closed by secondary suture, with the exception of a small central space where a small drain was left. After one more week the entire wound had healed.

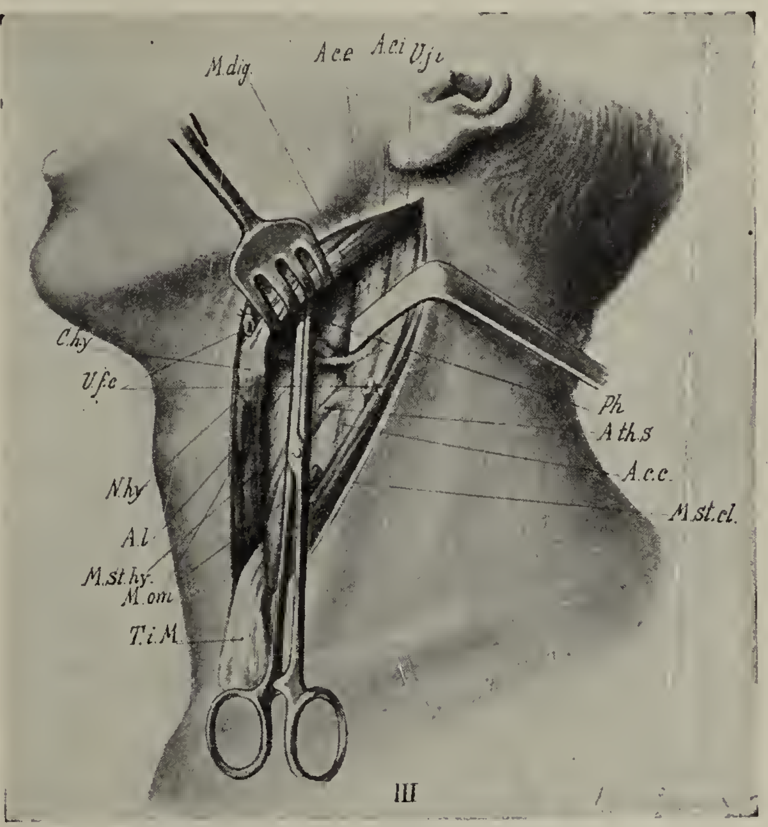

Fig. 3.—Illustration of the operation.

(Owing to lack of space it was impossible to include the author's two other cases.)

The typical operation reaching the original suppurative focus alongside the course of the vascular sheath is a logical procedure because it corresponds to the topographical anatomical condition. It should always be combined with opening of the mediastinum (collar mediastinotomy), followed by sealing or drainage of the same, depending upon whether it is in a healthy or diseased condition. At the early stage, conservative treatment may be tried, such as local antiphlogistic therapy, incision within the upper air passages, or, at times, also external incision without opening of the mediastinum. The patient must, however, be most closely observed and one must be ready to immediately perform the typical operation in case of emergency.

If the topographical anatomy of the region is mastered, the technic is simple. Acting under correct indication, and if the operation is performed in time, the result is always favorable. The typical external method for the relief of abscesses descending from the upper air passages should be preferably performed by the well trained rhinolaryngologist, who is thoroughly orientated by the all important pharyngolaryngoscopic examination and by his knowledge of the topographical anatomy.

Since I read my first paper on the subject before the Section on Laryngology of the New York Academy of Medicine, and especially since its publication in the *Laryngoscope,* I received numerous communications in regard to the fatality of these complicated and dangerous descending abscesses, when treated by the old methods. Fatal descending abscesses were reported by dentists (extraction of teeth and dental infection), otologists (mastoiditis, etc.), rhinologists (tonsillitis, peritonsillar abscess, phlegmonous affections, foreign body, and other conditions), and general practitioners (lues, tumors, and other conditions). It is my hope that through my endeavors a stimulus has been given to the profession for an early diagnosis and appropriate treatment of this life threatening condition. An apparently simple case should not be trifled with, and even a desperate one should be given a chance of the typical operation. This method is submitted to the general and rhinological surgeon for a fair trial, to pass upon it in cool judgment. Thus a measure concepted and advocated in enthusiasm will gradually find its right place in our armamentarium towards human sufferings.

64 EAST NINETY-FIRST STREET.

Climate in the Treatment of Pulmonary Tuberculosis*

By H. SCHWATT, M.D.,
New York,
Attending Physician, Tuberculosis Division, Montefiore Hospital for Chronic Diseases, and Bedford Sanatorium.

The belief in the therapeutic value of certain climates in the treatment of pulmonary tuberculosis has come down to us from time immemorial and, not unlike other beliefs founded upon faith and hope, has survived the mutations of the centuries. In our own country the opinion has become firmly implanted in the minds of the profession that there is something in the atmosphere of the valleys and mountain heights of the western climates that has a specific curative effect on the disease. That this is so is evidenced by the large number of consumptives who are advised to go there irrespective of the stage and activity of the disease, of its complications and of many other factors important in its treatment.

A number of years of experience in charge of a sanatorium for consumptives in Colorado has led me to believe that the practitioner in the east has not given the question sufficient thought and investigation and is thereby perpetuating a routine belief in the specific influence of certain climates, than which there is nothing more harmful.

There is considerable disagreement on the value of climate among men of wide experience in the treatment of tuberculosis. It is significant, however, that the division of opinion is largely limited by geographic lines, that is to say, that the great majority of the protagonists of certain climates are residents of these climates. It has been said that an honest paper on this subject still remains to be written and that a great deal of the glowing praise of certain climates in pulmonary tuberculosis is dictated by commercial interest. There is no doubt, however, that there is a tendency perfectly compatible with honesty of opinion to ascribe to the climate in which one lives particular therapeutic values. On the other hand, the rapid multiplication of sanatoria, within recent years, in climates for which no particularly brilliant claims have ever been put forward speaks for the conviction that altitude and other favorable climatic features of certain regions of the west are no longer to be considered of importance in the treatment of the disease.

Climate is a complex conception and is composed of many factors such as temperature, amount of sunshine and rain, dryness and humidity, frequency and velocity of winds, elevation above sea level, and the presence or absence of atmospheric impurities. The ideal climate for the treatment of tuberculosis would be one of comfortably cool temperature with moderate diurnal variations, a dry atmosphere with gentle breezes, free from impurities and at a moderate elevation. If we analyze the various climates recommended as of especial therapeutic value, namely, the high and arid regions of Arizona and New Mexico, the high altitudes of Colorado, and the varied climate of California, we find that they differ considerably and that none of them is characterized by uniformly favorable weather conditions throughout the year, nor throughout the day.

Admitting, however, that these regions offer favorable climatic conditions for a maximum opportunity for outdoor life, so universally recognized as of great importance for the consumptive, there is one factor common to the most popular of these which, as Fishberg (1) has so aptly put it, is "like a double edged sword," and of which I wish to speak in particular, namely, high altitude.

It has been asserted that high altitude is the greatest desideratum and the best single weapon in the treatment of pulmonary tuberculosis; that results are better at high altitudes than elsewhere and become better with every thousand feet of elevation gained up to six or seven thousand feet. It has been sought to demonstrate statements such as these by comparative studies of sanatorium reports at high altitudes and at sea level. The objections to this method are numerous; suffice it to say that the indefiniteness of our schemes of classification, the personal equation which unfortunately is so great a factor in the survey of cases of pulmonary tuberculosis and the many conditions aside from climate which influence the course of the disease make such studies practically worthless in proving or disproving the value of high climates.

---

*Read before the Harlem Medical Association, March 1, 1922.

We have the opinion of trustworthy authorities that tuberculosis is harmfully influenced by high elevations. Pottenger (2) states that the great majority of the tuberculous, especially after they have advanced beyond the initial stage, are at a disadvantage at high altitudes, and Fishberg (1) says that high altitudes are no panacea for tuberculosis.

Within recent years scientific evidence has been advanced to show that the value of high altitude in tuberculosis is due to its beneficial effects upon the cardiovascular, respiratory, and hematopoietic systems. If we sift the scientific data in support of the alleged therapeutic value of high altitudes we find that all is unproved hypothesis and conjecture from a clinical standpoint. Although we know a great deal of the compensatory physiological effects of high altitude on these systems in the healthy individual, it still remains to be proved that they are of benefit to the tuberculous and why. We do know, however, that the effect of deepening and acceleration of respiration due to lessened atmospheric pressure and the decreased quantity of oxygen may be extremely disadvantageous and distinctly harmful in a considerable proportion of cases by the increased amount of work thrown on the lungs and the heart.

On the other hand, it is no longer necessary to defend the statement that pulmonary tuberculosis can be successfully treated in any climate and that good results are not dependent upon altitude or even ideal climatic conditions, but upon skilled medical supervision and the influence of adequate physical and mental rest, a suitable diet, and above all sufficient means and time for treatment. Given these there is no doubt that excellent results are obtained in the health resorts of the western climates in suitable cases.

It should not be necessary to call attention to the futility of sending hopelessly far advanced cases with severe complications to high and distant climates in the expectation that they will be benefited. Yet the large number of such cases who go there by advice of practitioners is justification for emphasizing what should be selfevident. In general it may be said that the following types of cases are not suitable for, and as a rule do badly at, high altitudes, everything else being equal, and that the great majority of them are distinctly better off and have, bad as it may be, a better prognosis at low altitudes:

1. All unilateral and bilateral advanced, active, progressive cases with destructive processes and cavitation.
2. Extensive disease even of a chronic nature, especially with fibrosis associated with dyspnea, cyanosis, and marked emphysema.
3. Cases complicated by ulcerative laryngitis, definite intestinal and peritoneal tuberculosis, or persistent diarrhea.
4. Cases with the following nontuberculous complications irrespective of the stage of the pulmonary disease: cardiac disease, nephritis, albuminuria, arteriosclerosis, diabetes, bronchitis, and neurasthenia.
5. Cases, even without extensive disease of the lungs, with continued fever or with a pulse of 120 or more under absolute rest, especially if it is of impaired quality, and those with a tendency to profuse hemorrhages.
6. Cases even in the early stages of the disease of the asthenic type with markedly enfeebled vitality and digestion.

Patients in the initial stages of the disease without serious organic complications and functional disturbances are frequently benefited by change to a high climate after they have failed to respond to treatment under favorable conditions in the home climate. As a general rule, however, the prognosis in these cases is probably just as good in a low climate. Mere change of environment is frequently followed by marked improvement.

In any case strict individualization is of the greatest importance. The duration and extent of the lesion, whether it is active and progressive, certain symptoms and complications, the probable degree of favorable reaction and adaptibility to the change based upon a knowledge of the particular climate, and the possible injurious effects of absence from family and friends must be carefully considered. We must get away from the apparently prevailing idea that a positive sputum is the only indication for treatment in a high and distant climate.

It should be remembered that even under favorable conditions the period of acclimatization at a high altitude is often a crucial one. Apparently favorable lesions of moderate extent may become more active and progressive because of the inability of the weakened organism to meet the demands of the intensive reactions produced by the altitude.

It is also important to consider the possibility of reactivation of the disease after return to the home climate. My impression has been that after prolonged residence at a high altitude, patients, particularly if they are more or less advanced, do badly on return to a low altitude. Patients who do well should therefore be advised to remain in the high altitude. In general it is preferable to seek to effect a cure in the climate in which the patient intends to remain. It has also been my impression that relapses after an arrest has been achieved are not any less frequent at high than at low altitudes.

Above all, the economic status of the patient must be taken into account. Few consumptives of the working class can afford the expense of proper treatment for a sufficient length of time in a distant place. There is absolutely no excuse for advising far advanced indigent consumptives, and most of those we ordinarily have to deal with may be classed as indigent, to go to distant regions in search of that extremely doubtful and mostly hopeless thing—a cure of the disease. It has been my experience in Colorado that a large number of indigent, advanced consumptives come there under the impression that mere residence in this reputed Mecca will enable them to pursue their former or some other occupation or that they will be able to do it after a short term of sanatorium treatment. These mistaken ideas are very frequently engendered and encouraged by the practitioners. The consequences of such advice are extremely deplorable.

CONCLUSIONS.

In conclusion let me crystallize my remarks by stating:

1. There is no specific climate for the treatment of pulmonary tuberculosis; that no one climate is suitable for all cases of the disease and that it is becoming more and more the consensus of trustworthy opinion that tuberculosis can be successfully treated anywhere under a proper régime of rest, fresh air, diet and time.
2. There is no conclusive evidence to lead us to believe that high altitude is of any specific influence in the disease.
3. On the contrary, the great majority of the tuberculous and particularly those in the advanced stages are harmfully influenced by altitudes above from one thousand to two thousand feet.
4. Indigent consumptives, especially those in the advanced stages of the disease, should not be sent to high and distant climates.
5. It is important that these facts become of more common knowledge among physicians and the laity.

X Ray Study of Tuberculous Lungs

By THOMPSON FRAZER, M.D.,

and JOHN D. MAC RAE, M. D.,

Asheville, N. C.,

Consulting Radiologist, U. S. P. H. S. Hospitals 60, for Tuberculosis, Oteen, N. C., and 45, Kenilworth, Biltmore, N. C.

Although the employment of the x rays in the diagnosis of chest affections has been a recognized procedure for many years the significance which should be attached to x ray findings seems to be unappreciated by the profession as a whole.

The questions that are frequently asked are:

1. What is the value of the x rays in the diagnosis of tuberculosis?
2. Is it necessary that they be employed in order to establish a diagnosis?
3. If not, why should the patient be put to the additional expense which their use entails?
4. Do the x rays supply any information that cannot be obtained by other methods of examination?
5. Are the findings in accord with the results obtained by physical examination of the chest?
6. If not, to which should the greater importance be attached?
7. Will the x rays supersede the older methods of examination?

It seems to us that rather definite answers can be given to all of the above questions:

1. The employment of the x rays is a procedure of inestimable value in the recognition of tuberculosis.

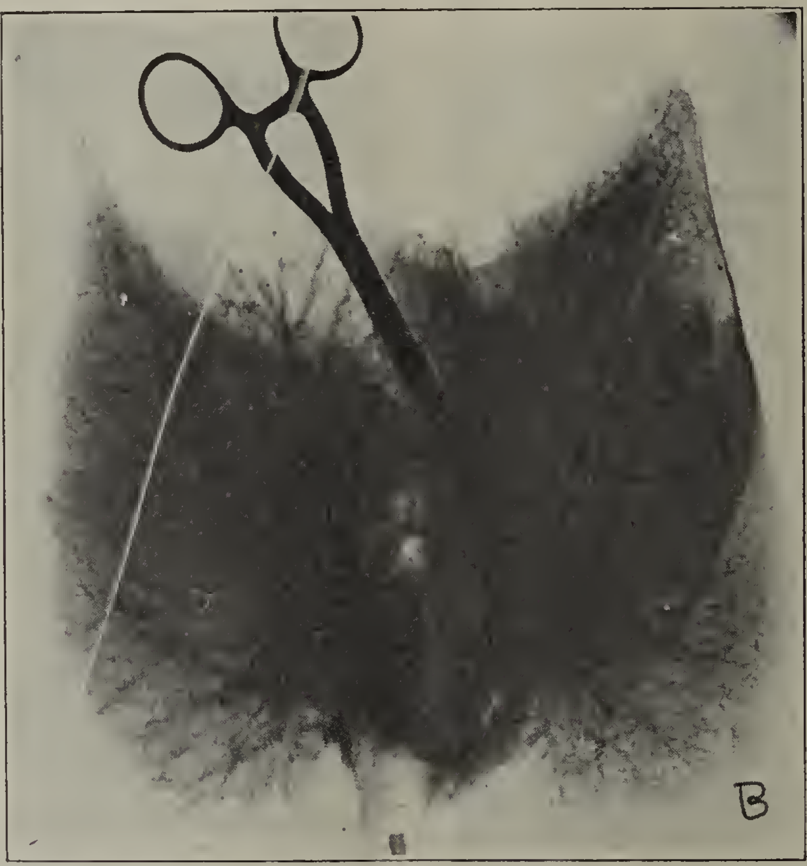

FIG. 1.—Lungs, postmortem, inflated, showing trunks. Posterior view.

2. In many cases, perhaps in most cases, the use of the older methods, history taking, physical examination, and examination of the sputum may suffice to establish a diagnosis. These methods, most available and most important, should never be neglected.
3. The additional expense involved in making stereoscopic plates is fully justified in that one obtains a more complete clinical picture of the individual case. Secondly, because we are furnished with a permanent graphic record which may be compared with subsequent plates.
4. X ray plates frequently disclose conditions which are not discoverable by other means.
5. The findings as revealed by the physical examination of the chest and by the x ray plates are frequently not in strict accordance; not uncommonly the röntgenoscopic examination reveals more evidence of pathology than would have been suspected from the physical examination alone.
6. The information supplied by x ray plates should be looked upon simply as so much additional evidence which must be properly evaluated. Under no condition should the symptoms or the results of

the physical examination be disregarded, nor a final from the physical examination alone.

7. The x rays, therefore, will not supplant the well recognized methods of examination. The röntgenologist, however, should go his full length in describing the lesion. He should make a diagnosis and express a prognosis from x ray findings alone, his opinion being unaffected by any knowledge of the physical findings. A correct value must be placed on the changes in the plates; the overlooking of the slighter changes and the reading of too much into the plates being the chief dangers to be avoided. There should then be a conference between clinician and röntgenologist, after which such changes may be made in the conclusions as may be indicated by the joint findings.

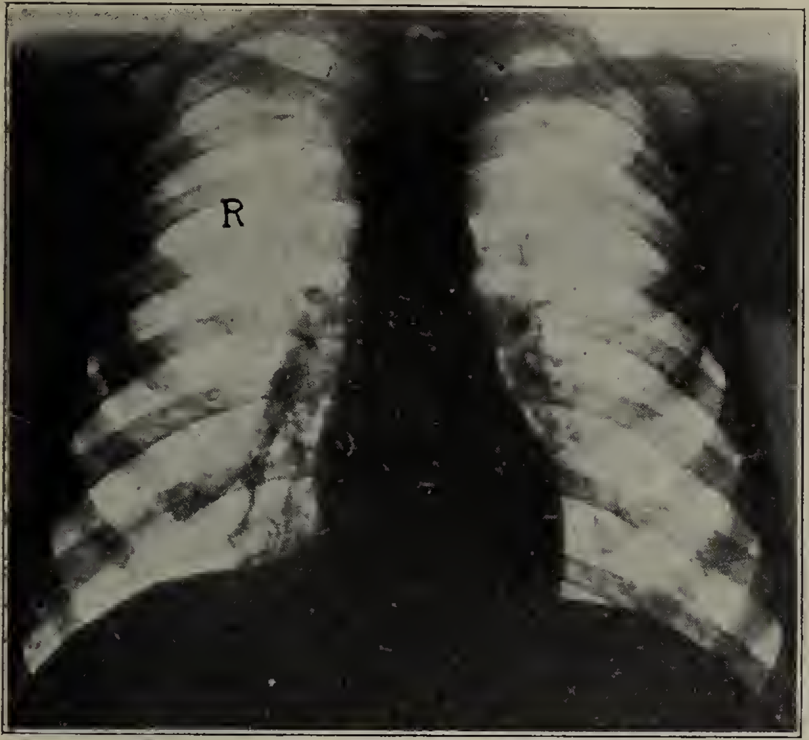

Fig. 2.—Normal chest. Symmetrical, phrenic angles clear, hilum shadows average size and density, lung fields clear.

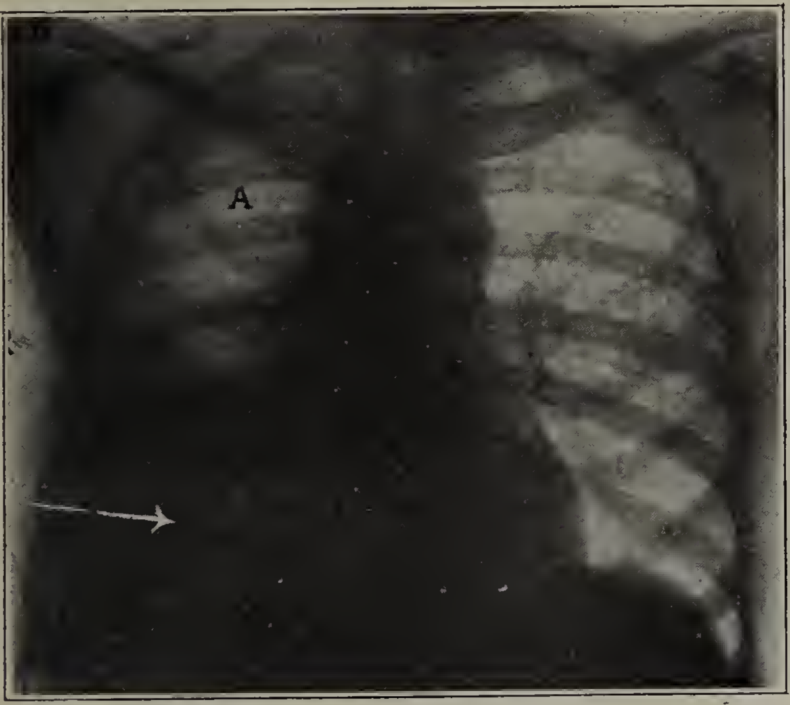

Fig. 3.—A, rib spaces narrow. B, thick pleura, effusion.

INTERPRETATION OF THE NORMAL CHEST.

Correct interpretation presupposes a knowledge of the normal chest (Fig. 1), and while the markings vary greatly in different chests there are some descriptive points which may be applied to all. The normal chest is symmetrical, with the trachea in the midline, and the heart and mediastinal organs occupying the centre of the chest; on each side of the mediastinum are the hilum or root shadows of the lungs, and radiating from the hili are the trunks which become less conspicuous until the terminal branches at the periphery are almost invisible. In x ray terminology the word trunk is often used. It means the shadow radiating from the root of the lung which is cast by a bronchus, its accompanying vein, artery, lymph masses and lymph channels with connective tissue binding them together. The peripheral branches are important in that it is there that we look for the early lesions.

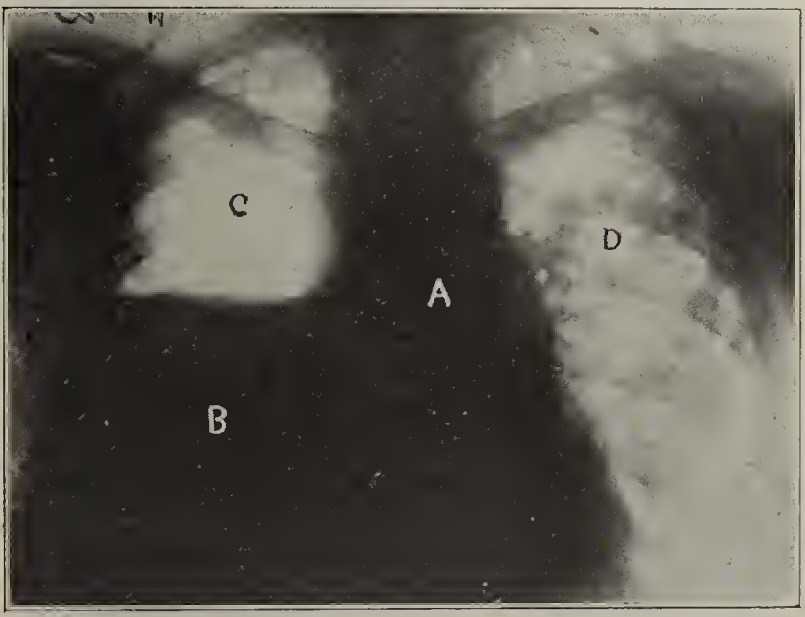

Fig. 4.—Hydropneumothorax. A, mediastinum pushed to left by fluid in right chest. B, fluid. C, air. D, infiltration, activity.

The right diaphragm is in front of the ninth rib and the left is slightly lower. The phrenic angles are clearly made out and should be fairly acute; the domes arch upward on each side. The lung field on each side of the mediastinum should be clear except for the hila and trunk shadows; shadows about the hila are of little importance unless they are very pronounced. Trunk shadows should be clear cut.

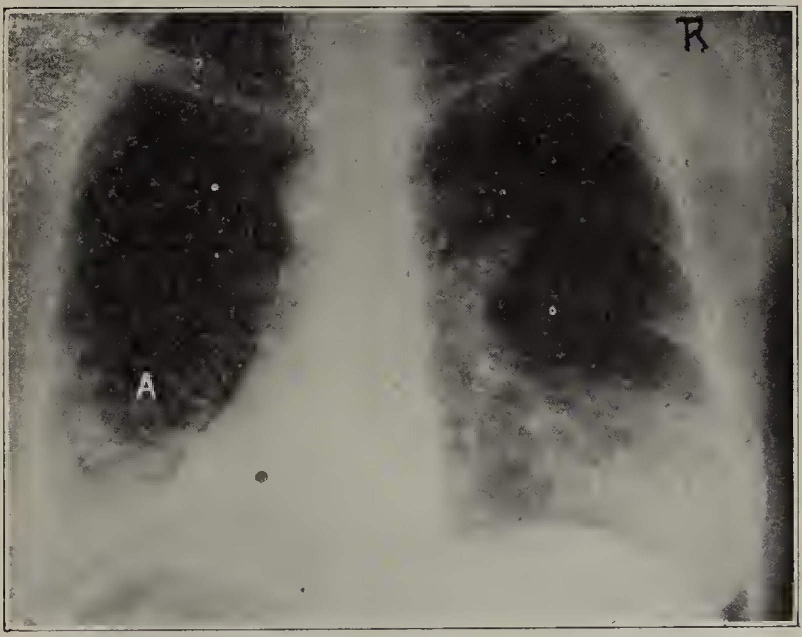

Fig. 6—A, cavity, nontuberculous.

Trunk shadows to the lower lobes are somewhat heavier and thicker than those to the upper lobes.

PATHOLOGICAL CHANGES.

The changes in the adult chest will be dealt with as follows: 1. Bony framework; 2, mediastinum; 3, the muscles and soft tissues; 4, the pleura, and 5, the lungs.

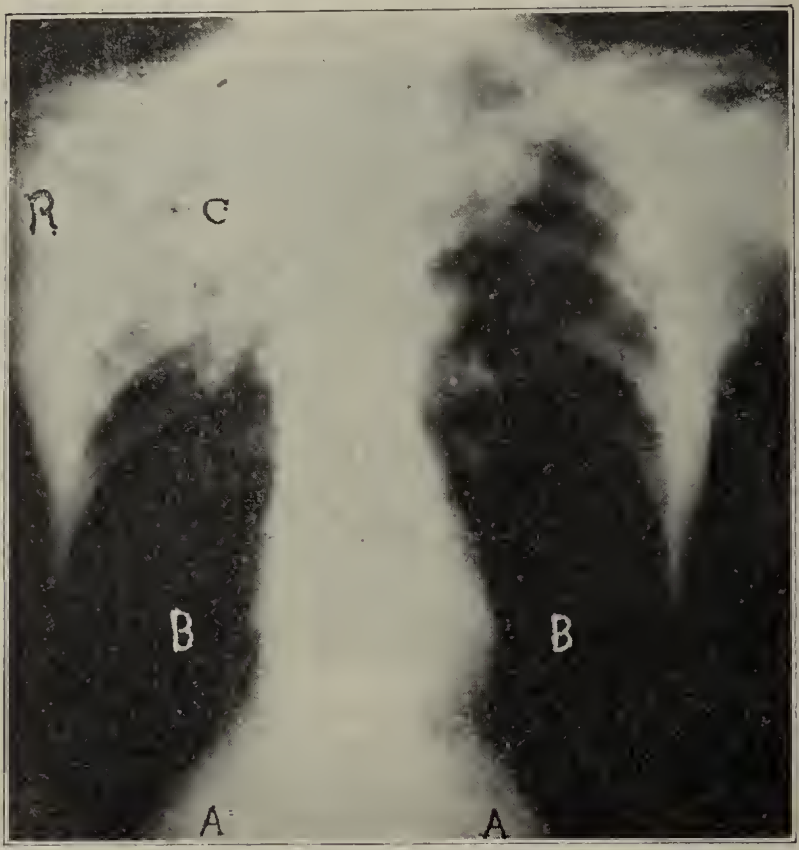

Fig. 7.—A, flattened diaphragm. B, emphysema. C, dense fibrosis.

1. Narrowing of rib spaces means flattening of the chest. This asymmetry may result from an acute pleuritis or from very chronic fibrous disease contracting the lung tissues and limiting expansion in respiration, or from markedly destructive lesions.

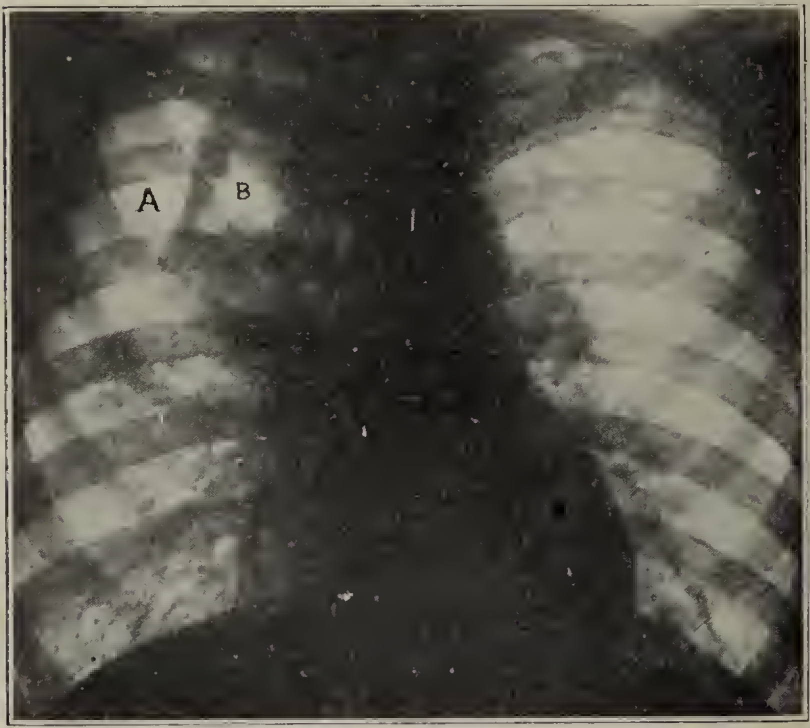

Fig. 10.—A, pneumothorax, artificial. B, cavity.

2. If the mediastinum is displaced to one side or the other it may be so as the result of fluid accumulating, or by reason of changes which produce contraction or destructive processes which impair the power of the lung to expand.

3. The diaphragm may be depressed by emphysema or drawn up by adhesions (Fig. 7). The mammæ in women may be so developed that they obscure changes in the bases of the lungs. Contrary to what is commonly expected, if the shadows of the pectoral muscles are prominent in the x ray plates we expect to find an emaciated patient rather than one who is of good muscular development.

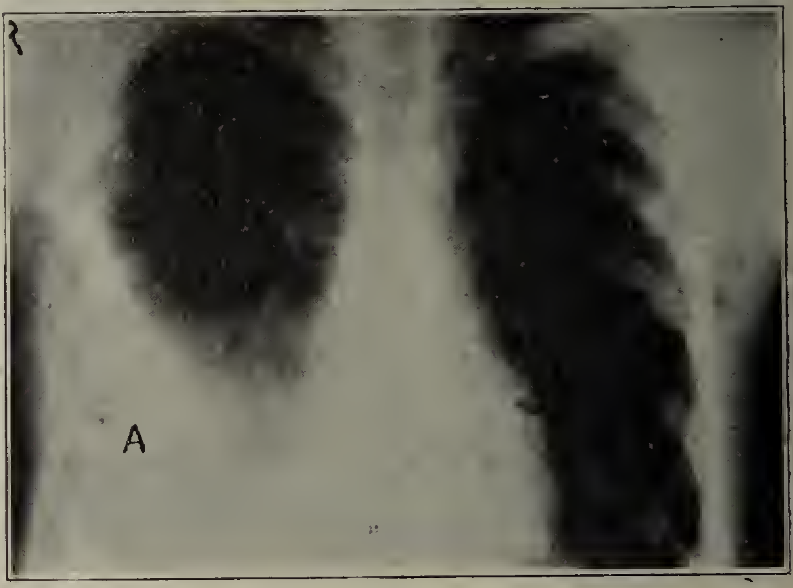

Fig. 11.—A, encapsulated fluid.

4. Pleural thickening is of every degree; fluid or air may be present in the pleural cavities. Effusion into the pleural cavity is common; it may be free or encapsulated (Fig. 11). Free fluid does not change its level quickly with change of position, but does so strikingly when air or gas exists in the pleural cavity with the fluid. Encapsulated fluid of course does not change its level. Thick pleura overlying fluid will cause it to be very difficult to say when the fluid has disappeared, either by aspiration or by absorption (Fig. 3).

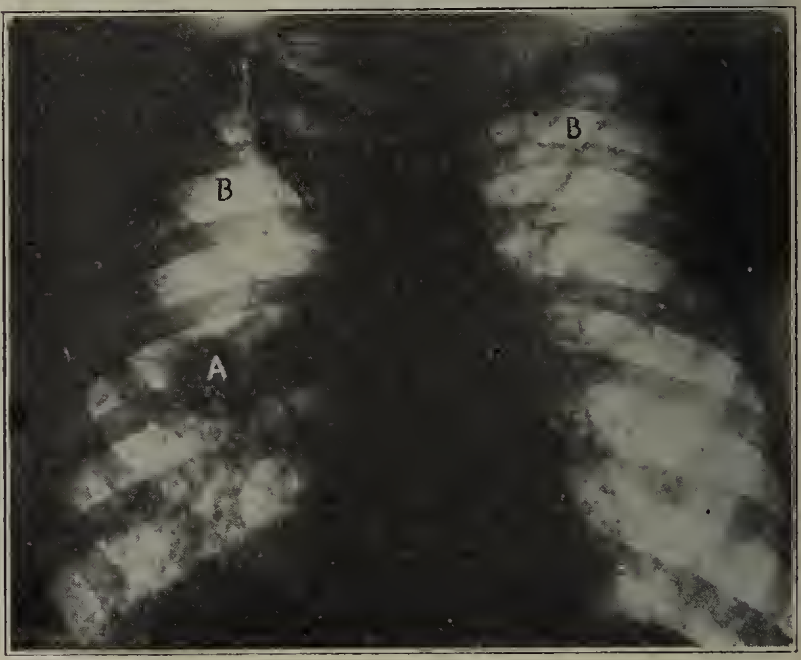

Fig. 12.—A, caseation. B, striated shadows, fibrosis.

Pneumothorax is either artificial or spontaneous. It is recognized in the plates when no lung markings are seen and the margins of compressed lung are made out. Unless adhesions between parietal and visceral pleura prevent, the air and gas in the pleural cavity will collect at the place overlying that seat of disease in the lung itself, especially if cavity exists (Barlow). Hydropneumothorax is a combination of the two above conditions (Fig. 4). The points above brought out direct our attention to the lung fields for a search of underlying pulmonary conditions, for as we have indicated, these changes are the secondary results which follow in the wake of pulmonary disease.

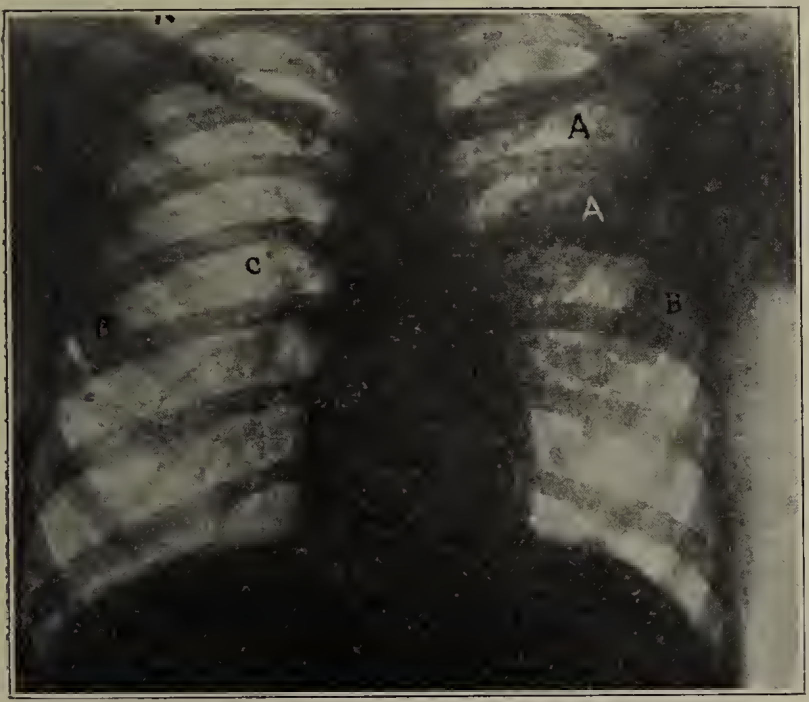

FIG. 13.—A, fibrosis and infiltration. B, Pectoral muscles. C, calcified lymph node.

5. A radiograph records the varying densities of the object depicted. A tuberculous lung undergoes certain changes which produce variable densities and by the character of these densities it may be determined whether infiltration, fibrosis, caseation or calcification exists.

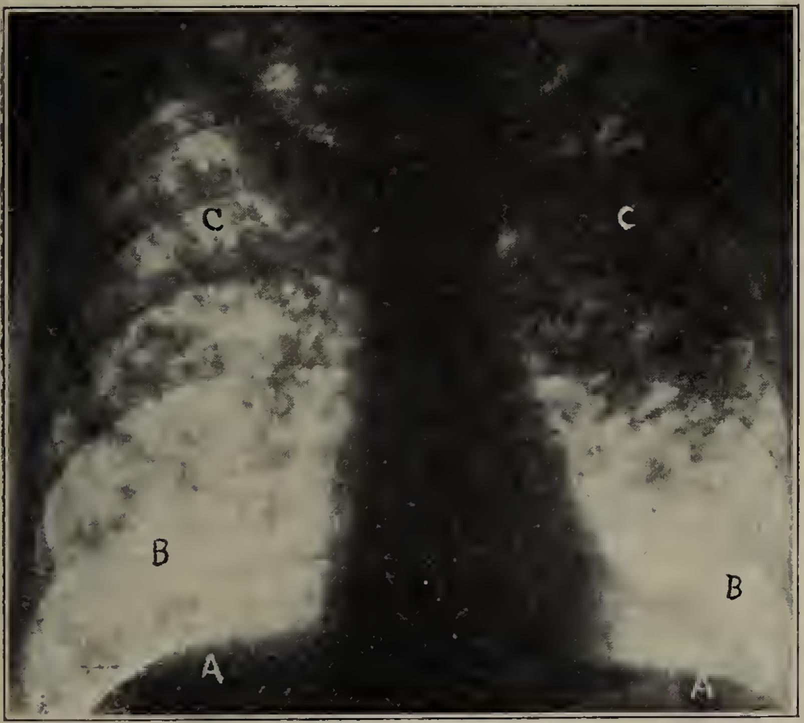

FIG. 16.—A, diaphragm flattened. B, emphysema. C, caseous bronchopneumonia.

Calcification is represented by shadows which are dense and clear in outline. The position in which calcification is common is at the root of the lung where the hilus nodes which have been the seat of tuberculous infection have undergone the process of being arrested by calcification. In the lungs of healthy persons it is rare to find one without calcified nodes about the hilum. These represent the early tuberculous infections which most of us have had and which give us the relative immunity which we possess.

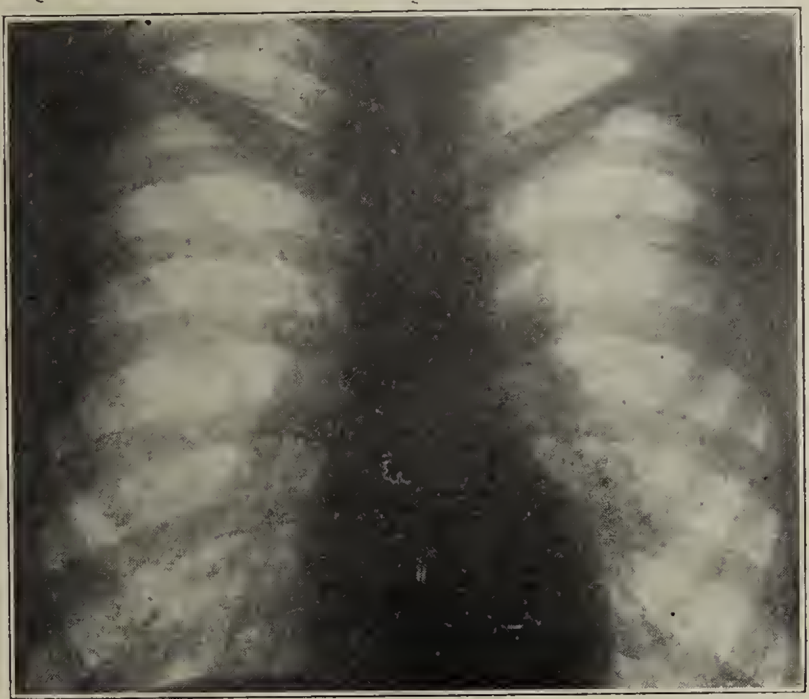

FIG. 17.—A, pneumokoniosis.

Caseation is the process which precedes calcification, if calcification is to occur, or which precedes cavitation if the patient's disease is going to progress. It represents masses of conglomerate tubercles which are not quite so dense as those of calcification and the distribution of caseation is different; more commonly it is distributed well outward from the hila into the parenchyma (Fig. 12). Caseation commonly takes place in small masses, hence the x ray picture of caseating bronchopneumonia is one showing many dense points widely scattered, or it

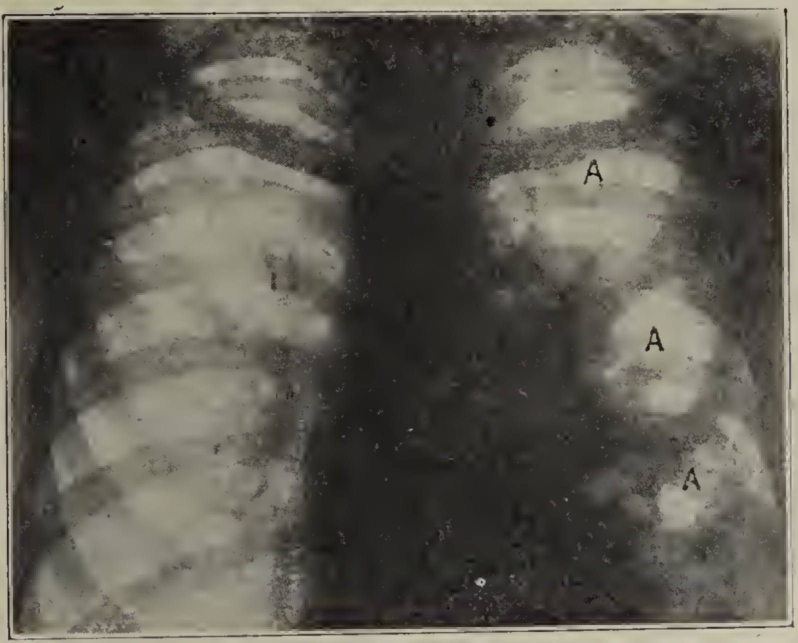

FIG. 19.—A, multiple cavities.

may be collected into groups. Sometimes a whole lobe may be of uniform density with caseation (Fig. 16), or a few small caseating points only may be seen within the lobe.

When conglomerate tubercles caseate and then break down by liquefaction, necrotic material is expelled from the centre of the mass and a cavity is formed. Cavities at first do not have well defined walls but if the patient develops good resistance, firm well defined walls form.

Cavities are commonly seen among the terminal branches of the trunks of the upper lobes (Fig. 10). They rarely occur near the hila before destruction has become extensive (Fig. 19). A cavity may contain fluid and air. When this is so the fluid level will change as the patient's position is changed, just as it does in hydropneumothorax. Cavities are not necessarily tuberculous in origin (Fig. 6).

Fibrosis may produce dense shadows but it is laid down in a characteristic way. When fibrosis takes place it represents the scars left by the healing of tuberculous processes which have not advanced to a state of caseation. In the main, fibrosis is found among terminal branches of a trunk where active infiltrative processes had been arrested (Fig. 13). The shadows representing fibrosis are generally laid down in lines and are described as linear markings.

Infiltration: When a lesion is still active but undergoing fibrosis there will be cast shadows which are streaky, and others which are more or less flocculent; the flocculence represents parenchymal lesions where larger or smaller masses of air cells are filled with debris—mucus, epithelial cells—which is the condition found in early tuberculosis.

Activity: We think that from the changes described it is possible to discuss with a certain degree of intelligence the question of activity, for the shadows of a distinctly healed tuberculosis are different from the shadows cast by an active process. In the former the shadows are clear cut and striated, in the latter, soft hazy and flocculent in character and having illdefined outlines.

Emphysema is a condition of low density which should be discussed here. It is generally compensatory. In the presence of chronic fibroid phthisis and also in some other conditions, air cells dilate, stretch and lose their power to return to their original size. If emphysema is general the thorax will bulge in all its diameters; before this extreme condition is reached, the diaphragm is depressed and flattened. The acuteness of the costophrenic angles is lost as the domes of the diaphragm are pushed downward, and the x rays penetrate such lungs with greater ease. The radiograph of such a condition is characteristic (Fig. 7).

NOT ALL SHADOWS TUBERCULOUS

Now there are many conditions which may produce shadows other than tuberculosis, and peribronchial tuberculosis is a term which should be discarded, for the bronchi become thickened and cast fuzzy shadows following any of the diseases of childhood, pertussis, measles, scarlet fever, etc., as well as from pneumokoniosis (Fig. 17), and chronic lung affections. If peribronchial tuberculosis exists it is usually secondary to more pronounced lesions elsewhere in the chest.

It is characteristic of tuberculosis that its lesions are located in one or both upper lobes and that the different lesions are of different age and different densities. When uniformly thickened trunks are recognized it is unlike tuberculosis and we think of it as being secondary to influenza or some other lung condition.

That condition known as brown induration, which results from pulmonary stasis secondary to cardiac disease, casts a shadow similar to that of influenza. We have seen lungs the seat of actinimycosis which were strikingly like tuberculous lesions; the differential diagnosis being made by the clinical history as well as by the examination of the pathological specimen.

Specific disease of the lungs has, in our experience (MacRae), accompanied tuberculosis oftener than it has existed alone, as numerous postmortem examinations have shown, and in spite of much that we have read we do not feel that differentiation between the two processes can be made readily.

SUMMARY.

We believe that a röntgenographic study of lungs is so valuable that no examination should be regarded as complete without this procedure.

A Pulmonary Sign in Acute Infections of the Biliary Tract.—D. P. D. Wilkie (*British Medical Journal,* June 10, 1922) calls attention to the pulmonary symptoms and signs sometimes accompanying primary and focal lesions in the upper abdomen. Crepitations may be heard at the right base of the lung in quite a number of cases of acute biliary infection, and also with infection of the bile ducts and where the gallbladder is not the chief seat of the trouble. There are three theories as to the etiology of this finding: 1, a spread of the infection from the gallbladder or bile ducts by way of the peritoneum through the lymphatics of the diaphragm to the pleura and the base of the lung; 2, that reflexly, from irritation of the sensory fibres of the phrenic nerve, the diaphragmatic excursions are diminished on the right side, resulting in diminished expansion of the right lung and hypostatic congestion of that lung, and 3, that the lung condition is a blood infection settling in a part of the lung in which the expansion is restricted by the factors mentioned above. In twenty-three acute surgical cases of biliary infection, this basal congestion was found present in twelve and absent in eleven; in two cases pleural friction was also present. In no case did any pneumonic complication follow the operation, and in one case pleurisy with effusion was found on the following day. The mortality was nil. Ether anesthesia was used in twenty-four cases and chloroform in seven. The author concludes that in a patient with pain in the right costal margin and round the right side of the chest, the crepitations or pleural friction at the right base does not preclude but supports the diagnosis of acute biliary infection and that these signs are not contraindications for operation, but on the contrary they will be relieved by surgical removal of the primary focus of disease.

The Present Status of Radiation Treatment of the Tonsils

By CARL F. ROBINSON, M.D.,
Barre, Vermont.

The resourceful physician, finding that his usual method of treating a condition is closed to him, tries to improvize a way of doing the same thing in another manner. Thus Witherbee (1), in his search for a method of treating diseased tonsils in patients exhibiting heart disease, hemophilia or some other condition contraindicating operation, experimented with the x ray and found that many cases responded—an atrophy of the tonsil taking place and an absorption of the immature lymphatic cells in the follicle which lessening the depth and resulting in a distortion of the crypt caused at the same time an eversion and an evacuation of the crypt contents.

My work along his lines produced results similar to his, but early in 1921 I was led to experiment with radium because it seemed to me that a direct application of the rays would eliminate the possibility of any injury to overlying structures. I also desired to apply the softer rays directly to the tonsil, which is impossible with external application of the x ray —the softer rays being filtered out to avoid skin reaction.

A series of 156 cases can now be reported. In 145 cases, six weeks after the radium application, a small atrophied tonsil only was seen and only by pushing back the anterior pillar. Symptoms of neuritis and rheumatism were reported as disappearing about two weeks after treatment. Five cases were unsatisfactory—the tonsil being fibrous and radiation therefore unsuitable. However, the tonsil showed a smoothed out appearance and in one case hearing was improved materially. Eight cases are in course of treatment.

My technic is simple, consisting of the introduction of two 12.5 mg. radium needle directly into the centre of the tonsil under local anesthesia. The entire throat is swabbed over with a two per cent. novocaine solution—a procedure which is necessary in order to prevent gagging. The needles are left in place from two to three hours.

Recent literature contains several references to the radiation of tonsils and it is interesting to follow the different methods. Each worker trying in his fashion to cause an atrophy of the tonsil and thus benefiting humanity.

Simpson (2) applies radium directly to the tonsil using a thirty mg. flat applicator of double strength. This is held directly against the tonsil by means of a long instrument for an hour. He is quoted: "With this original technic it is perfectly remarkable how quickly the tonsils begin to shrink and show other atrophic changes. A mild reaction which turns the tissue white is to be seen where the radium is held. This slight irritation of the tonsil disappears in two to three days. In one patient with a temperature of 101°, exudate in the crypts of the enlarged protruding and inflamed tonsils, cervical glands of the neck the size of half an orange, associated with malaise and loss of appetite, the picture was changed in one week and after a single treatment. The enlarged glands disappeared in three weeks, and only a part of the tonsil was to be seen when the anterior pillar was pulled to one side." Simpson used x ray treatment externally at the same time that the radium was used.

Radium needles are introduced directly into the tonsillar tissue by Wells (3). Quoting from his article, "For the purpose of comparison it has been my habit to begin always with the larger tonsil and the effect is impressive when at the next setting we observe that the proportion has been reversed and that the previously larger tonsil has now become the smaller one. In addition to the mere reduction in size, a difference is remarked in the appearance of the organ. A tonsil that previously presented an irregular nodulated surface, or perhaps has been of the socalled ragged or spongy type, now appears smooth, firm and pale. Very important proof that atrophic process has successfully attacked the diseased lymphoid structure is found in the progressive lessening of colonies of bacteria and especially in the fact that we can no longer obtain pathologic exudate from the crypts on pressure. The author has histological proof of the effect of radiation in bringing about cellular atrophy. I have had sectioned and examined microscopically tonsils that have been radiated and then removed surgically at varying intervals of time afterwards. With sufficient dosage it is certain that we can obtain an atrophy of the tonsil which may liken to the normal physiological atrophy and that all physical evidences of disease are made to disappear."

Williams (4) reports cases treated by direct application of the radium applicator with results similar to those quoted above by Simpson. Delavan (5) writes that "very small amounts of x ray were sufficient for the reduction of the lymphoid tonsil, doses so small that no injury resulted to other parts from its application. J. H. Murphy, Craig, Hussey and Sturm (6) have published interesting reports favorable to x ray treatment. Hickey reports that the throats of diphtheria carriers can be sterilized with suitable x ray treatment.

There is a feeling among many physicians that, because the region of the neck contains so many important anatomical structures, radiation treatment may do harm. This feeling is not shared by radiologists because of their daily use of much heavier doses used in treating malignant conditions of the throat and neck. Boggs writes: "Literature fails to reveal the report of any case of untoward effects of radiation on the thyroid, parathyroid, pituitary or parotid gland."

One thousand milligram hours of radium is an ordinary dose given for metastatic glands in the neck and an x ray dose of 5 Ma., sparkgap nine inches, filter 3 mm. aluminum, with a distance of ten inches for six to seven minutes is regularly given if radium is not at hand. Thus a much smaller dose given in treating the diseased tonsil surely cannot do harm to adjacent tissues. Bergonie and Tribondeau's law is that "immature cells and cells in an active state of division are more sensitive to radiation than are cells which have already acquired their fixed adult morphological or physiological characters." If we accept the above law or the teachings of Dominici that elementary cells are receptive or sensitive to hard rays and the wellknown selective action of radium then fear of radiation treatment of tonsils must be laid aside.

Turning from the safety of this treatment to the effect of radiation upon bacteria we find that Murphy (7) reports forty-six patients with tonsils both hypertrophied and otherwise pathologically altered and some of whom had in addition adenoid masses and lymphoid deposits posterior to the pillars of the fauces which were given treatment. In all but four cases the treatment was followed by marked atrophy by opening up and drainage of the tonsillar crypts. As this process progressed, the previously enlarged tonsils assumed a smooth and normal appearance and hemolytic bacteria—streptococci, and staphylococci chiefly—which were often present in the affected tonsil, disappeared usually within four weeks of treatment.

Probably the bactericidal action of radiation is derived from the secondary beta rays and the alpha rays—chiefly from the beta rays which are produced in the tissues during the passage of the gamma and x rays. McKee says that these rays are able to interfere markedly with cultures even to the point of complete destruction. However, this subject has few references of carefully controlled experiments and presents a fertile field for much discussion.

I have seen a neuritis of long standing clear up in four weeks after radium treatment of a diseased tonsil. I have also seen cases of acute and chronic rheumatism become free of this disease after atrophy of the tonsil by radiation. At present we (8) are introducing a solution of iron into areas to be treated by radiation with the hope of increasing the production of secondary beta rays. We have noticed that an acutely infected tonsil reacts much better than the chronic, possibly because of the presence of more blood with its iron content in the tonsil, the iron increasing secondary beta radiation.

Radium seems to us to be the method of choice because only one application is usually needed. It may be augmented with an x ray treatment externally. Ewing says that "Radium can be relied upon to do the same thing under the same circumstances." The x ray is not quite as reliable but, with the advent of the Collidge tube, technic may be carried through with a smaller chance of error than formerly. Children are afraid of the noise of the x ray but I find that they rather enjoy the external radium treatment because of the novelty of having their head bandaged up.

The manner of application of radium differs with different men but the object is always the same and results similar. I still think that the introduction of the radium needle directly into the tonsil with supplementary x ray treatment to the neck is the method of choice because it affords an ideal application of the agent.

A Case of Ludwig's Angina

By DAVID H. LEVY, M.D.,

New York.

Because of the rarity of this condition, the novelty of the treatment employed and the exceptional result obtained, I feel justified in publishing this single case.

CASE.—G. P. E., aged thirty-three, retired on the evening of May 19, 1922, feeling perfectly well. He awoke on the morning of May 20th feeling quite ill. There was soreness and pain in the floor of the mouth and great difficulty in deglutition, and pain when he attempted to open his mouth or to swallow. This condition grew steadily worse.

I saw the patient for the first time on the evening of May 21st, and examination showed that he was unable to open his mouth more than one quarter of an inch and attempting to swallow caused severe pain. His temperature was 103° and pulse 120. Direct examination showed a hard induration in the submaxillary region, under the inferior maxilla, more marked under the point of the chin. He could not protrude his tongue. A provisional diagnosis of Ludwig's angina was made. On the following morning (May 22nd), the patient was much worse, all signs having increased in severity. The entire floor of the mouth was swollen, hard and indurated; the tongue was congested and so swollen that only the tip could be protruded between the teeth; the temperature and pulse were the same. A marked point of tenderness was present under the tongue in the floor of the mouth on the right side. The patient looked septic. I had him removed to a private sanitarium, and considered my provisional diagnosis confirmed.

Because of the results obtained in various infectious conditions by the intravenous use of neutral achriflavine-pro injectione in the wards of the City Hospital, I decided to give this drug a trial and to postpone surgical interference, at least for a few hours longer. At 4 p. m. twenty c. c. of a one per cent. solution was injected intravenously.

I returned to the sanitarium at 12 p. m. planning to interfere surgically if the condition had progressed any further. But, as the patient stated he was much more comfortable and the pain had markedly decreased, and since the temperature had fallen to 101°, I decided to postpone any surgical interference for the time being.

The next morning (May 23rd) the patient was markedly improved; the temperature was 100°, and all signs were receding. The patient was given another twenty c. c. of a one per cent. solution and he continued to improve rapidly throughout the day and following night.

The next morning (May 24th) he was able to open his mouth widely, the swelling of the tongue had practically disappeared; he was able to protrude the tongue much more freely and without pain. He stated that he was perfectly well. I decided to give him a third injection to complete a cure. At this time the temperature was normal. The patient was kept in the hospital until the 28th under observation, and was then discharged completely well.

In view of the brilliant result obtained, it would appear that this drug should be given a trial by the profession in a wide variety of infectious conditions so that its field of usefulness as well as its limitations may be established.

Peritonsillar Abscess of Unusual Location*

By ADOLPH I. SCHWARTZ, M.D.
New York.
Chief of Clinic and Surgeon Ear, Nose and Throat, Stuyvesant Polyclinic; Visiting Otorhinolaryngologist, People's Hospital.

Peritonsillar abscesses are of common occurrence. They are frequently met with and diagnosed by the general practitioners without any difficulty. Following an acute tonsillitis where the symptoms at the end of a few days instead of being ameliorated, become more severe, there is almost always a suspicion of an abscess forming in the throat.

Often the diagnosis is made before the patient is examined by the characteristically full, thick, muffled guttural voice; the inability of the patient to open the mouth (fixation of the lower jaw in itself is symptomatic and almost pathognomonic of the affection); by excessive painful deglutition; by the general appearance of the patient who is showing great weakness; by pain radiating in the ear of the affected side with attempts of swallowing, and other symptoms. On examination, which is accomplished in many cases with great difficulty owing to the fixation of the lower jaw and gagging, one can see the anterior pillar of the fauces and the soft palate of the affected side to be intensely red, swollen, often edematous, projecting far more forward than those of the opposite side provided this is not involved.

These characteristic symptoms are produced and easily accounted for from the very location of the abscesses. It is out of the province of this paper to go into detail of these peritonsillar abscesses of common occurrences—that is, those pointing toward the upper pole of the tonsil.

We will limit ourselves to the cases that follow, where some of these symptoms have been lacking and where the diagnosis has not been made for many weeks following an acute tonsillitis. Although the literature of acute peritonsillar abscess is quite voluminous, it may be interesting to state that in making a careful search of textbooks and medical periodicals which appeared in the past twenty-four years, no case similar to the ones to be reported has been described.

It was assumed that the most careful tonsil work has been done during this period. If one's experience counts for anything, I have never before seen a case of this type in seventeen years of practice either in the clinics or in private practice.

REPORT OF CASES.

Case I.—Mrs. R. K., aged forty-two, was seen in consultation on January 30, 1922. The following history has been related by the attending physician. The patient was taken ill with acute tonsillitis four weeks ago. Fever and inflammation of the tonsils subsided after a few days, but the pain on swallowing became greater every day on the right side, and at the time when the patient was seen it was so intense that she could not partake of any food, fluid or otherwise. There was snoring and choking at night and general symptoms of distress. The patient answered questions with a peculiar muffled, guttural voice. The mouth could be opened pretty freely. On examination the throat looked normal, no signs of an inflammatory nature could be noticed in the tonsillar region on either side. Therefore, the diagnosis of abscess has been dismissed by the physician in the case. There were only two symptoms: The voice of the patient and the excessive pain in deglutition which were suggesting the presence of pus somewhere in the throat.

It was noted that when the tongue was pressed down to inspect the lower pole of the right tonsil, great pain was elicited, and the patient will jerk away or push me brusquely aside. The index finger was introduced and a very painful spot, at the lower pole of the tonsil between it and the base of the tongue was palpated. There was no pulsation present. Fluctuation could be decidedly ascertained at the next introduction of the finger. Pressure was abruptly made into the fluctuating mass, which was hidden by the popping up of the tongue, and a fair quantity of foul smelling pus followed. The patient felt relieved and after a few minutes could swallow water while I was present. I have not seen the patient since but was informed subsequently that she had a quiet night following the evacuation of pus; began to eat and gradually had fully recovered in a few days. Incidentally it may be said that this was the first case in my experience. I have never before met with a throat abscess at this site.

---

*Read at the Clinical Meeting of People's Hospital, October 11, 1922.

Case II.—Mr. M. M., fifty-six years old, clothing packer. was brought to my office on March 28, 1922, by Dr. L. Friedman. The man was pale, emaciated, had lost considerable weight. The physician gave the following history: Illness began with an acute tonsillitis about two months previously. The acute condition in the throat subsided but the pain was so intense in the last two weeks that the man was prevented from eating. A swelling on the right side of the neck, below the angle of the lower jaw, painful to palpation, was noticeable. An x ray taken March 25, 1922, visualized moderate induration of the tissues on a line parallel with the third and fourth cervical vertebræ on the right side and a shadow which suggested a possible localized pus pocket. The peculiar voice mentioned before was present as soon as the patient began to talk but he could open his mouth well and on inspection nothing abnormal could be noticed, neither on the soft palate nor on the anterior pillars. Pressing the tongue down great pain was experienced and the examination had to be interrupted for a great while. The index finger introduced at the base of the tongue between it and the right tonsil, a fluctuating mass was felt. There was no pulsation. The diagnosis of abscess was made, a free incision performed and pus followed the knife. A drain was inserted and after a few days of drainage the man made an uneventful recovery. The swelling of the neck gradually subsided. At the end of six days it disappeared and the patient was discharged. It is to be regretted that the circumstances were such that no examination of pus could be made.

CONCLUSIONS.

The following practical conclusions can be deducted:

1. Peritonsillar abscesses pointing down the inferior pole of the tonsil are extremely rare.
2. Only two symptoms: Intense pain on swallowing and the characteristic guttural voice persisting for weeks, suffice to lead us on the track for diagnosing the abscess at this location.
3. When the patient lacks the pathognomonic symptom of fixation of the lower jaw, can open his mouth freely and the upper part of the tonsil and adjoining soft palate look negative on inspection, don't discard the diagnosis of peritonsillar abscess.
4. Always examine the lower pole of the tonsils by pressing the tongue down and in towards the median line with a tongue depressor.
5. When pain is elicited by this manipulation and a mass is present, always palpate the mass with your finger.
6. Make sure there is no pulsation, for fear of meeting with an angioma or any other vascular tumor.
7. Ascertain fluctuation.
8. When the latter is present incise and drain and the results will be most satisfactory to both patient and physician.

Diagnosis of Optic Neuritis Due to Sinus Disease

By JOHN N. HOFFMAN, M.D.,

Canton, Ohio

To definitely decide that visual defects are due to disease in the nasal sinuses should be the result of considerable careful investigation. If a thorough routine examination was always consistently carried out the number of cases diagnosed as such would be considerably less. In addition fever patients would be subjected to nasal sinus surgery.

According to Fuchs the various causes of intraocular optic neuritis are as follows: Brain diseases, as tumor, abscess, multiple sclerosis, acute and chronic meningitis; lues; acute infectious diseases; disturbances of nutrition; acute anaemia from loss of blood; lead poisoning; heredity; and inflammations or tumors in the orbit or developing upon the nerve.

Lead, alcohol, tobacco and other toxic agents cause a retrobulbar neuritis. To these may be added toxic absorption from various sources in the body including the teeth, tonsils, bowels, and nasal sinuses. In dealing with the effect of diseased nasal sinuses we find we have the posterior ethmoid and sphenoid sinuses which are so located anatomically that there is direct connection between them and the optic nerve. We shall assume that we are dealing with a patient whose eye condition is due to disease in the posterior group of nasal sinuses and the necessary steps in the differential diagnosis will be outlined.

In taking the history one should get all the information possible as to the beginning and duration of the visual trouble (which may be monocular or binocular) if the present is the first attack or whether others have preceded it, and its association, if any, with other disorders of the patient's health. In the cases studied by the writer where the diagnosis seemed clear-cut almost all were monocular. His occupation, surroundings and habits should be asked about to aid in discovering the absorption of any toxins. The visual acuity should be recorded and the usual ophthalmic examination made. The opthalmoscope may reveal no lesions or the changes may range from a slight pallor of the nerve head to those of a marked neuroretinitis. The majority of patients studied have had no changes in the fundi—if seen early. In a few patients it was thought that the temporal side of the disc may be somewhat paler than normal. Negative ophthalmoscopic findings are very frequently the result.

Perimetry should always be employed, if visual acuity allows, because the visual field changes are characteristic in disease of the posterior sinuses, involving the optic nerve. The visual fields, in patients where the posterior sinuses are diseased, depend largely upon the amount of involvement of the nerve. Careful examinations of the early cases will often show an enlargement of the blind spot and a central scotoma for colors; the two are soon connected in more advanced cases unless the progress of the inflammation is stopped. As the disease progresses the scotoma becomes absolute. The form fields are often irregularly contracted and are not of value in a diagnosis. The taking of fields upon numerous occasions is strongly advised and the condition of the fields affords an efficient method of judging the progress of an inflammation of this sort after treatment or operation. If visual acuity is markedly lowered rough tests will give an approximate idea of marked defects in the fields. Laboratory tests, with especial stress upon lues, should be carried out as speedily as possible. The other tests upon the body fluids should always be made. A complete physical examination should follow and a neurological examination should determine the condition of the central nervous system with especial reference to the brain. Granted that the foregoing tests are negative we still have a difficult field in examining the nasal sinuses.

Clinical examination and x ray will usually easily determine the presence of purulent conditions. These offer but little difficulty in diagnosis. In estimating the presence or absence of nonpurulent conditions, which are hyperplastic, we should make several careful examinations. The relation between the nasal septum, the middle turbinates and the lateral nasal walls should first be considered. The condition of the nasal mucosa is often of value; a boggy hypertrophic condition indicates some chronic disturbance. Hypertrophy of the inferior turbinate also often indicates nonpurulent sinus disease. The nose has no pus but more than the usual amount of mucous may be present. Granular pharyngitis is often associated with this type of sinus disease. Bimanual palpation of the floor of the mouth may reveal the presence of enlarged and tender lymph glands which are often an indication of nasal sinus infection. The luetic origin of this type of nasal change must always be kept in mind. A diagnosis of hyperplastic sphenoiditis and ethmoiditis should not be made upon one finding but upon a combination findings and after several examinations of the nose. Applications of cocaine and adrenalin to the region around the middle turbinate occasionally causes some change in vision temporarily which is helpful in reaching a diagnosis. The impaction of a middle turbinate tightly against the lateral wall is especially stressed. The X ray may be of considerable help in nonpurulent sinus disease but careful technic is an essential and the findings cannot always be relied upon.

In the differential diagnosis the history, if carefully taken, will usually exclude toxic amblyopias. Perimetry in this condition generally shows bilateral pericentral scotomata and the blind spot may or may not be included. A typical condition according to Peter is the presence of an absolute scotoma in a large relative area. In optic nerve atrophy the visual fields have a variety of changes but the color fields are always much more contracted than the form fields. Scotomata may or may not be present. Space will not be devoted to an analysis of the fields found in the different types of optic nerve atrophy as this would entail considerable description. Hysteria is marked by concentric contraction of the form fields and reversal of the color fields. In the different conditions with which choked disc is associated the perimeter will show varying findings. Some of these, in early cases, will closely simulate the visual fields found in posterior sinus disease, and are referred to in order that the extreme care needed in diagnosis may be illustrated. Perimetric findings, while invaluable, are not an absolute means of diagnosis and must be combined with the other examinations.

At times, patients will be encountered who present some general condition as lues plus the clinical signs of posterior sinus involvement and the perimetric findings of an associated neuritis. I feel that one's judgment is severely taxed in these cases in order to correctly decide to what cause the visual impairment is due. In doubtful cases I feel that treatment or operation on the sinuses should be done because vision might be retained which otherwise would be lost.

When the patient has been thoroughly examined as suggested and pathological changes as detailed are discovered only in the nose I feel that one is justified in urging prompt treatment or operative procedures upon the posterior sinuses. The objection has been raised that a complete examination occupies too much valuable time but the examination, as outlined, with the exception of a few of the laboratory tests, can be completed in a fairly brief interval. Useless temporizing is not urged but an accurate effort should be made to find the cause of the condition. The following points are to be especially emphasized:

1. Optic neuritis, indistinguishable by the ophthalmoscope, has a variety of causes among which are infections in both the anterior and posterior nasal sinuses.
2. Visual field findings are the only characteristic of neuritis due to diseased posterior sinuses and are of the same type in purulent and nonpurulent infections.
3. The occurrence of neuritis due to diseased nasal sinuses is relatively small if all proper means are used in making a diagnosis.
4. Great caution must be exercised in making a diagnosis of hyperplastic sinusitis and thorough examinations should exclude other pathology before deciding that the sinuses are the cause of the neuritis.
5. Reports of visual improvement following sinus operations should not be considered conclusive until some months after the operation; vision is frequently temporarily better for a time due to the local blood loss even though some other cause than sinus disease is present.

1001 New Harter Bank Building.

Editorial Articles

EIGHTY YEARS OLD.

This is the Eightieth Anniversary of the founding of the *Medical News*, one of the four great medical journals which have been consolidated into the New York Medical Journal and Medical Record. The four are the *New York Medical Journal*, the *Philadelphia Medical Journal*, the *Medical News*, and the *Medical Record*.

Many changes have occurred during these eight decades of medical journalism. A great deal of valuable material has been published which has been of inestimable service to the medical profession. Out of the flux has come the present fusion which has brought strength and experience. From growth and centralization the New York Medical Journal and Medical Record has been evolved. We realize our responsibility and are ever striving to better this journal in order to improve its standard and make it more useful.

EVOLUTIONAL LEVELS IN THE NERVOUS SYSTEM

Sir Frederick Mott, writing in a recent number of the *Lancet* on Body and Mind: the Origin of Dualism, includes an interesting and illuminating discussion of the doctrine of Hughlings Jackson's levels. Mott says: "We may consider that there are three evolutional levels in the nervous system, and this hypothesis is supported by comparative anatomy and the effects of functional and organic disease of the nervous system. The lowest level is present in all animals and subserves the primal instincts of selfpreservation and preservation of the species. It consists of two parts: 1, the vegetative nervous system, consisting of two systems, a, the involuntary autonomic or parasympathetic, and, b, the sympathetic, with which are associated the ductless glands, and which controls and directs the bodily needs and functions concerned with gratification of the appetites and desires connected with the instincts of selfpreservation and propagation; 2, the protopathic sensorimotor nervous system, which controls the reflex activities for protection against pain and injury, including injurious degrees of heat and cold.

"The second level is the discriminative sensorimotor level. In the vertebrate series, we find two great groups: 1, macrocosmatic, in which the nervous structures that are especially developed are those connected with smell and taste; and, 2, microcosmatic, in which the senses of sight, hearing and touch are especially developed. The archicortex of the cerebral hemispheres is highly developed in the former, the neocortex in the latter. The projection centers of these senses are around the primary fissures.

"The third highest level is the psychic level, in which there is a great development of the cortex of the brain, and which in man far exceeds in development that of the largest anthropoid apes. *Pari passu* with this great development of the cerebral hemispheres, is a bodily development far surpassing in excellence all the lower animals: viz., erect posture—by which the forelimbs are no longer used for progression—and perfection of the hand, whereby it becomes, not only the instrument, but the instructor of the mind, for, guided by vision, it is enabled to create and make the most of varied mental adjustments to environment and control the forces of nature. By the creation of graphic and articulate language, which have simultaneously progressed, has been built up a great social heritage constituting an endowment to civilized man, whose organ of mind is, however, no larger nor heavier, and possibly potentially no better than that of the men who dwelt in caves 50,000 years ago, whose only common mode of expression was, it may be conjectured, mainly by vocal sounds, gestures, and facial expression, a primitive, universal, emotional language, understood by all peoples.

"Now, in idiots who are incapable of articulate expression and abstract thought, we find only the two lower levels properly represented; the development of the anatomical basis of psychic level—i.e., the millions of cells in the cortex—is arrested in development and we have a condition, then, of amentia or absence of mind. If we examined sections of the cortex, we should find the supragranular layer of pyramids especially affected. This layer, as Bolton has shown, is developed later than the infragranular layer. Moreover, I have shown that, as you rise in the zoological scale of vertebrates, it is this layer that increases in depth and number of cells. Simple dementia or loss of mind may be associated with a limited destruction of the anatomical basis of mind—viz., the highest psychic level—and, the two lower levels being more or less intact, the habitual acquired sensorimotor reactions may remain and the individual then may behave as an automaton in response to environmental influences and bodily needs. Every part of the body is represented in all the three evolutional levels, and, as Hughlings Jackson taught, the last to come evolutionally is the first to go. The three physiological levels are functionally interdependent. The highest level, upon which awareness and volition depend, is able to act through the second discriminative sensorimotor level to alterations in the streams of sensation from the external world; while the third and lowest level evolutionally is concerned with the involuntary vital functions of the body, and therefore constitutes the basic source of the desires and impulses connected with self preservation and propagation."

INOCULATIONS FOR SMALLPOX.

In a time when the word smallpox is heard more frequently and when the efforts of a large number of persons, including the socalled educated—even socalled educators—in some of our cities recently visited by the ominous sickness, are put forth to prevent its prevention, a little history of past experience with this disease and efforts toward its control are especially interesting.

For there is, no matter in what department of life, nothing so illuminating and useful as history. Would that it were taught in our schools, not the names of the Kings of England nor of the Presidents of the United States nor of the Wars of the Roses nor of the Rebellion, but of more intimate matters in human affairs. A little chapter on inoculation for the smallpox would stand for an example.

The introduction of this practice quite upset the intellectual centre of our country—Boston, lining up the clergy, the schoolmasters, physicians—everybody. The Mathers, Cotton and Increase, led the fight for inoculation—in fact, it seems probable that it was through the efforts of these two witch fearing worthies that the process was introduced into the country, for they first received word of it, and then encouraged the bold Dr. Boylston to begin his work.

The word inoculation, in connection with smallpox, will doubtless be interpreted by many a reader as meaning vaccination, for most of us doctors have had our schooling in history sadly neglected. We must confess that it was not until fifteen years after medical school days that we learned the meaning of this term.

Inoculation for smallpox was supposed to have begun in China, but at any rate it came into use in Europe about 1713. Boston was always in the lead in good things, and it was in 1721 that Boylston began his work. Inoculation consisted in nothing more or less (and the less needs emphasis) than the introduction, not of cowpox material into the uninitiated, but the transmission of the real thing—matter from a smallpox pustule to a person who, presumably, had never known the disease. True, hit or miss efforts were made to minimize the danger, by passing the material from person to person—arm to arm, as it was called—by diluting the contagious matter with water and by choosing virus in a crude or unripe stage.

Boylston had no such suggestions (of doubtful use) to guide him, for the Boston physician who received a communication from the Royal Society telling of the methods employed abroad, joined the ranks of the antiinoculators and refused to allow others to see the English report. Boylston continued his labors, despite the professional and lay war that waged so violently that Cotton Mather said he "never saw the Devil so *let loose* upon any occasion. A lying spirit was gone forth at such a rate that there was no believing any thing we heard." Boylston was himself "put to a great fright by the clamor or rather the rage of the people." The clamor and rage originated, not as does presentday agitation against vaccination, but from objection to man's attempted interference with the workings of Divine Providence. In thirty years Boylston had inoculated 1752 persons. In about the same period Kirkpatrick of Charleston, S. C., had done some eight hundred.

The significant thing in all this is that anyone should dare to inoculate and, even more, that anyone should wish to be inoculated, for, as someone has put it, there seemed to be but one advantage, namely, that one could have the disease at his own convenience, and at a time when there were enough not sick of the plague to take care of him. Still, it may be that the disease was less deadly when introduced through the skin than when contracted in the ordinary way, for Boylston had only thirty deaths from his inoculations, and Kirkpatrick had but eight.

The outstanding feature to be read between the lines is that smallpox was such an omnipresent and frightful affair and so uncertain a risk that one might as well have it in as safe a way and at as convenient a time as possible and have it over with. So reasoned Ben Franklin when his child died of the disease, that he might better have had him inoculated and run that risk rather than run the risk of contracting the disease otherwise.

Inoculation added to Jenner's brilliant work with the cowpox vaccine, for, to test the efficacy of this protection, he inoculated some of those he had previously vaccinated, and—behold—there was no result—the protection by vaccine was assured.

INTRACAPSULAR OPERATION FOR CATARACT

The wide divergence of opinion concerning the merits and demerits of the intracapsular method of extracting cataract devised by Lt. Col. Smith, of the Indian Medical Service, has found expression so often that we have really grown tired of the subject. Perhaps this because its merits have been dwelt upon so strongly by those who have studied with and come under the strong and winning personality of Col. Smith, while the demerits have been pointed out by those whose experience with the operation has been comparatively slight. However, this may be, it is a pleasure to read a paper by an intracapsular operator who uses the method in ninety-five per cent. of his cases and yet appreciates that it is subject to closer limitations than those which have been presented by its distinguished and genial originator.

Dr. H. T. Holland contributes to the *Indian Medical Gazette* for August a paper on Some Contraindications to the Intracapsular Operation for Cataract Based on Eight Thousand Cases. Eight thousand cases may be a small number according to Indian standards, but it is greater than many American surgeons can accumulate in a lieftime and one sufficient to furnish an observant surgeon definite conclusions. He states frankly that he is an advocate of the operation, that he believes it would have fewer opponents if its advocates would admit its limitations, and that he has learned by sad experience the kinds of cataract upon which it should not be performed.

The only classes of cataract considered by Smith unsuitable for intracapsular extraction are 1, congenital; 2, juvenile up to thirty years of age, and secondary or after cataract. Holland adds to these several other classes. He considers that the operation should not be performed on a full blooded, fat, plethoric individual with large, prominent so-called ox eye as he has found a decided tendency to escape of vitreous in such cases. Then come cases which appear normal, but resist legitimate pressure to rupture the zonule. He has difficulty in defining the legitimate amount of pressure and says that experience alone can enable the operator to decide when he has reached the limit, but he is convinced that when it is very difficult to rupture the zonule and the lens does not present at the corneal incision as it should, it is better to reinsert the speculum and perform capsulotomy than to court disaster in the shape of a large escape of vitreous material.

His third class of cases would seem to be a part of the second, as it includes cases of double cataract in comparatively young persons with dark hair, in whom the zonule often proves very resistant. In these cases if pressure is persisted in too long the zonule breaks as it were with a snap and out comes the lens followed by vitreous. His fourth class is composed of cases in which glaucoma is present either as a complication or a cause, cataract in glaucoma or glaucomatous cataract. In the former he agrees with Smith as to the advisability of a large iridectomy, but differs from him as to intracapsular extraction three months or so later. He includes among these cases those in which the tension is slightly elevated, and prefers extraction with capsulotomy as affording less danger of choroidal hemorrhage. Glaucomatous cataract is seldom fit for operation at all, but in the few cases in which it is advisable he prefers capsulotomy. Finally he prefers capsulotomy in traumatic cataract, because of the decided tendency of vitreous to escape when the intracapsular operation is performed.

It is evident that Holland considers loss of vitreous a much more serious complication than does Col. Smith, an opinion in which he will have the support of most, if not all, American surgeons. His suggestion that "it is more than possible certain operators may have been unsuccessful in some of their intracapsular work from ignorance of these contraindications" sounds rather more than plausible.

HIGH BLOOD PRESSURE AND ITS TREATMENT

It is notorious that high blood pressure is extremely prevalent nowadays, at any rate, if it is not very much more common than formerly, a great deal more is heard of the condition than ever before. It may be, and probably is the case, that everything to do with the circulation is done more exactly than formerly and that consequently more cases are diagnosed.

But it seems fairly certain that there is a greater number of cases proportionately of high blood pressure than there was, say, thirty years ago. It is said by some that hypertension is made a bogey of now, and that it is not nearly so dangerous as it is stated to be by many heart specialists. This may be true to a certain extent, and the danger of the condition may be exaggerated; at the same time there is no evading the fact that it is sufficiently dangerous to give rise to alarm on the part of the sufferer. It is a danger signal warning to go slow. Hyptertension is a condition intensified by modern cultivation.

Modern methods of living, while it must be allowed that the human system is wonderfully adaptable, tend to affect the circulation. However, the argument propounded here is not that high blood pressure is greatly due to the wear and tear of modern existence involving an immense strain on the nervous system and affecting the heart prejudicially, but that it is largely owing to intestinal toxemia, a sequel to disorders of the gastrointestinal tract and to intestinal stasis in particular.

Dr. N. Mutch of London contributed an article to this journal February 15, last, in which the thesis was set forth that alimentary toxemia arising from chronic intestinal stasis, is a frequent cause, perhaps the most frequent cause of heart affections and of high blood pressure. So far as high blood pressure is concerned, Mutch holds that there is no doubt that toxins of some nature are found in the intestines and when absorbed cause a serious rise in the blood pressure. Sir James Mackenzie advises that in the treatment of affections of the heart, it is advisable to overlook symptoms, heart affections are usually symptoms, find out the primary cause and treat it.

Mackenzie believes that a goodly proportion of heart complaints have their origin in toxemia. Dr. R. McNair Wilson is of the same opinion and indeed heart affections are generally classed as toxic and infective. Moreover, the origin of the toxic form is, in the opinion of many authorities, in the gastrointestinal tract. Alimentary toxemia will cause high blood pressure, or is a potent factor in its causation. These cases may be recognized by the excessive amount of putrefactive products in the urine.

Again many authorities assert that an excess of uric acid in the system is the main cause of high blood pressure; some go further and assert that it is the sole cause; and as excess of uric acid is chiefly brought by alimentary toxemia it is obvious that the rational treatment is to try to put the gastrointestinal tract into good working order as well as the urinary tract and the kidneys which are both involved in the toxemia. Diet, hygiene of the bowels, intestinal disinfection and so on will go a long way, but at the same time, the urinary tract should be disinfected and free elimination from the kidneys established.

The retention in the body of large amounts of uric acid in the system must be abolished, and with this end in view, not only must the gastrointestinal tract be thoroughly cleansed, but as said before the urinary tract must be rid of its excess of uric acid and putrefactive products and the kidneys encouraged and urged to eliminate freely—such a course of treatment is following Sir James Mackenzie's advice to treat underlying causes if it is granted that gastrointestinal disorders are underlying causes of high blood pressure.

CALCIUM IN METABOLISM

A sufficient supply of the mineral salts in the body is essential to proper metabolism and to health. Absence of mineral salts means death and a supply insufficient to control the metabolic equilibrium means ill health. Of the mineral salts the calcium salts are the most important and lack of these upsets the metabolic balance. The vast importance of a sufficiency of calcium in the human economy is now beginning to be thoroughly understood. In many diseases and conditions of ill health the amount of calcium in the system is insufficient for the purpose of proper metabolism, while certain diseases are mainly due to a want of calcium even though this may not be the primary or underlying cause. Rickets are brought on undoubtedly by a deficiency of calcium, whatever the cause of this deficiency may be, want of sunlight, unhealthy environment, inadequate or unsuitable and so on. Tuberculosis again, at any rate, in some forms, is largely owing to the decalcification of the system. It must be borne in mind too that the parathyroid glands have a very intimate relationship with calcium metabolism. The consensus of medical scientific opinion now is that the action of the parathyroids is antagonistic to that of the thyroid and that they play a special part in the fixation of calcium in the tissues. If therefore the parathyroids are not working in a normal manner, the nervous system, owing to the deficiency of calcium, will become irritable and tetany may follow.

Dr. Hurst in the special number on endocrinology of this journal gave an example of a case of extreme nervousness cured by the oral administration of dried extract of parathyroid oxgland. In the *Lancet*, November 4 last, Dr. I. C. Graves sums up the value of the administration of calcium. With regard to chronic sepsis, it would appear that calcium plays a part in the reexcitation of the activities of the mobile defences of the body in conditions of chronic sepsis, and, after the removal of the cause of the chronic sepsis by the induced reaction, calcium dries up the exudates. When a chronic toxemia is present Grove and Pines found that the tonic calcium of the blood becomes deficient. Improved peripheral circulation is a characteristic response to treatment by calcium and this improvement may similarly obtain in the alimentary tract leading to improved digestive processes. When calcium is administered the diminution of night sweats is evident, a result associated with a lessening of chronic septic absorption. Reference has been already made to the fact that the withdrawal of calcium from the body leads to an increased irritability of the sympathetic nervous system and Graves states that the administration of calcium does away with the hyperirritability.

Lastly, it is pointed out that nutritional gain is a feature of cases showing calcium deficiency, treated by the administration of calcium. Moreover, while diet will to some extent remedy a calcium deficiency in the system, and while, of course, a diet rich in lime salts is indicated in such cases, diet alone is not curative. Not only then must the diet be rectified but when decalcification is obvious, calcium must be administered. Rickets and tuberculosis are the diseases in which decalcification most manifests itself but in convalescence from nearly all the acute infections decalcification is present. Also in many of the chronic diseases an inadequate amount of the lime salts is a distinctive symptom. In fact decalcification exists in all diseases and conditions in which nutrition is at a low ebb and in which there is deterioration of the nervous system, for the simple and sufficient reason that a lack of calcium means that metabolism is at fault, consequently food is not being digested and assimilated as it should be, the body is not nourished properly and the want of calcium injuriously affects the nervous system. It cannot be too strongly insisted that calcium in adequate quantities is essential to normal metabolism.

NEUROLOGY.

The *Paris Médical* for October 7, 1922, is devoted to neurological material. The material has been carefully assembled and it is a number which should be in great demand. The following is a list of the authors and subjects appearing in this special issue: Jean Camus, *La Neurologie en 1922 (Revue annuelle)*; Barré, *Les sympathalgies de la périphérie des membres;* Foix et Nicolesco, *Valeur diagnostique et prónostique, modifications du tonus au cours des paraplégies d'origine médullaire;* André Thomas, *A propos du tonus musculaire, l'extensibilité et le réflexe antagoniste;* Roshem, *De l'art de choisir ses rêves;* Barbillon, *Agonie et anesthésie;* G. Pranzo, *De l'empirisme et des superstitions en médecine chez les Arabes de la Tunisie;* Mousson-Lanauze, *La médecine dans Aullu-Gelle;* Jean Camus, *L'impöt progressif sur la natalité;* Peytel, *Escroquerie et accident du travail;* Rabier, *L'honnête hommer.*

◆

Obituary.

DR. ALBERT HENRY BUCK,

of New York.

At the regular meeting of the New York Otological Society, held November 28, 1922, the following obituary of the society's first president, Dr. Albert Henry Buck, was ordered to be incorporated in the minutes and also to be submitted to the medical journals for publication: There are comparatively few, perhaps, who read this brief sketch, who will recall a courteous, kindly gentleman, whose smile was reassuring and whose countenance instilled a confidence in the strength and the will to give aid to one in need; a scrupulously honest, lovable man—one of the grand old men of medicine—Dr. Albert H. Buck, who has just passed on.

He was born in New York City October 20, 1842, the son of Dr. Gurdon Buck, one of America's noted surgeons. Switzerland, his mother's native country and where he received a part of his early education, remained throughout his life the Mecca to which all roads led whenever it was feasible for him to travel. He was an Alumnus of Yale College, class of '64; of the College of Physicians and Surgeons, class of '67, and of the New York Hospital.

After his internship in New York Hospital he went abroad and in Germany and Austria, under Politzer and others, devoted his entire time to the study of the ear and its diseases. After his return to New York his indefatigable labors resulted in the early recognition of his ability and skill. He was made an aural surgeon in the New York Eye and Ear Infirmary in 1872, and, after half a century, death severed his connection with the institution as a consulting aural surgeon. For a number of years he was consulting aurist to the Presbyterian Hospital; lecturer and later professor of otology in the College of Physicians and Surgeons, medical department of Columbia University. He was fourth president of the American Otological Society, being preceded in office by Dr. Henry D. Noyes, Dr. D. B. St. John Roosa, and Dr. Clarence J. Blake, and was the first president of the New York Otological Society.

Dr. Buck's literary tastes and linguistic knowledge were employed in the editing of the voluminous and epochmaking medical works of the American edition of *Ziemssen's Cyclopedia of the Practice of Medicine,* eight volumes, first edition, 1887; second edition, 1890; the *American Practice of Surgery,* eight volumes, 1908; also the American translation of Stricker's *Manual of Histology,* one volume, 1872; and *Hygiene and Public Health,* two volumes, 1879. These were apart from his many contributions on otological problems in the medical journals. His work on *Diseases of the Ear* was peculiarly the individual result of his own observation and study. The third and last edition was published in 1898.

After retiring from the practice of otology his virile mind demanded occupation and so, after much research in the libraries of this country and those of abroad, Dr. Buck gave to the world in 1917 a most entertaining and instructive book, *The Growth of Medicine from the Earliest Times to About 1800.* It was the first book published by the Yale University Press on the Williams Memorial Publication Fund, and in 1920, in the seventy-eighth year of his life, he completed his labors with *The Dawn of Modern Medicine,* also published under the auspices of the Williams Memorial Publication Fund, by the Yale Press.

His modesty and reticence were so marked that to the many he was unknown, but fortunate were those who could claim the friendship of this true and lovable man. Many, many will be benefitted because he lived and worked as befitted a man of science.

Committee.

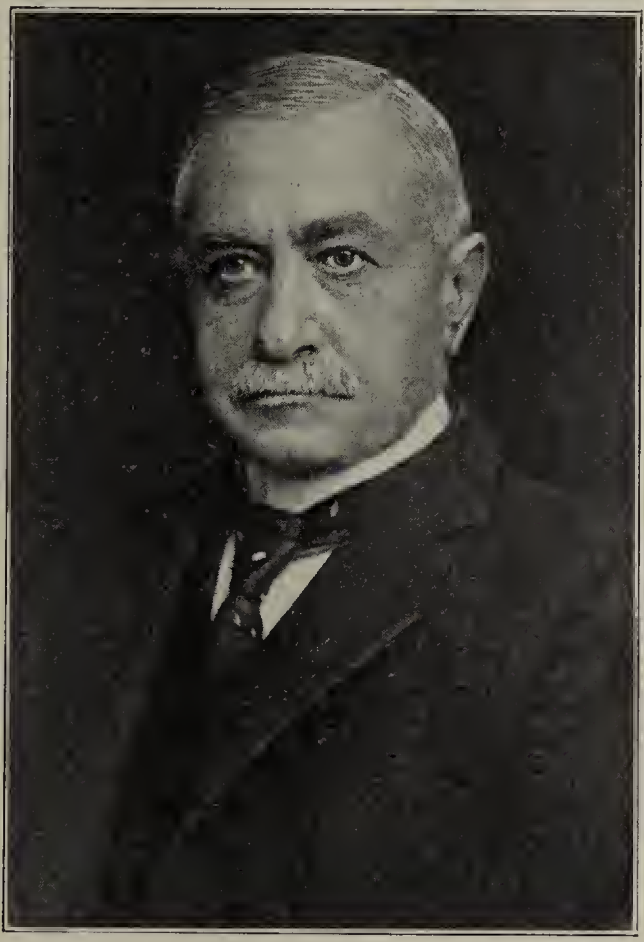
JOSEPH EDCIL WINTERS, M. D.,

of New York.

The recent death of Dr. Joseph E. Winters, Prof. Emeritus of Diseases of Children, Cornell University Medical College in the City of New York, removes one long recognized as among the foremost pediatricians and diagnosticians of his time.

Dr. Winters was born at Minnisink, Tioga County, New York, January 11, 1848, and died October 4, 1922. From childhood he possessed an earnest desire to become a physician, and entered upon the study of medicine with Dr. George P. Cady, of Nicholas, Tioga County, New York. Coming to New York City in 1869, young Winters matriculated at the Medical Department of the University of New York, from which he was graduated in 1872.

In 1873-4 he became House-Surgeon at Bellevue Hospital, and in 1874-5 House-Physician. From 1875 to 1879 he acted as Assistant Pathologist and Curator to Bellevue Hospital. An ardent student of anatomy, he enjoyed special advantages as demonstrator and instructor under that most brilliant master, Prof. Darling of the University Medical School, holding the position from 1873 to 1885. In 1875 he became assistant to Prof. Alfred L. Loomis in teaching physical diagnosis in Bellevue Hospital. From 1881 until 1898 he was a member of the teaching staff at the University Medical School, as lecturer, clinical professor and professor of the Diseases of Children. In 1882 he was appointed attending physician, Department of Diseases of Children, to the Demilt Dispensary, then a leading institution of its kind, and, in 1877 under Lefferts and others, the first to develop a regularly organized system of instruction for graduates in medicine, the prototype of the present Post Graduate School. Here it was that Dr. Winters began his distinguished career as a specialist in pediatrics. In 1898 he withdrew from New York University to accept the professorship of Diseases of Children in the Cornell University Medical College. This position he held during the period of the War until the summer succeeding the armistice, when he resigned.



DR. JOSEPH EDCIL WINTERS

While still an interne of Bellevue Dr. Winters became associated with the late Dr. Joseph W. Howe, professor of Surgery at the University Medical School and master of the most successful "Quiz Class" of the time. For many years the fame of "Winters' Quiz" was unrivaled. His ability as an instructor amounted to genius. Consequently, he attracted the very best students and thus acquired a large and influential following of loyal and lifelong friends. "Winters' Quiz" was discontinued only when, through radical changes of policy, the colleges took over such instruction to themselves.

Dr. Winters was the author of various monographs on the feeding and care of infants and children, on rheumatism, and diseases incident to childhood. These papers were landmarks in the progress of pediatrics. No one of his time contributed more effectively to the wellbeing of the young. The expression "A Winters' baby" became a generic term descriptive of fine development and perfect health.

His capacity for work was extraordinary, his industry untiring, always with unswerving honesty seeking the truth. Of quick perception, full and ready knowledge, and remarkable diagnostic ability, his uprightness, gentleness, sympathy and rare unselfishness made him the ideal physician and the trusted friend.

Thus his distinguished career was no mere freak of fortune. Clearly it was the result of four fundamental elements, namely, fine heredity and personal physique; uplifting environment; rare earnestness of purpose; exceptional intellectual power. Beginning absolutely upon his own resources, he succeeded because success with such qualifications was inevitable.

In addition to his other activities Dr. Winters was visiting physician to the Willard Parker and Riverside Hospitals, Christ's Hospital, Jersey City, and St. Joseph's Hospital, Yonkers; also to the Mount Vernon and Flushing Hospitals and emeritus consultant to the Hebrew Sheltering Guardian Society. He was a Fellow of the New York Academy of Medicine, of the American Medical Association, of the American Pediatric Society, a member of the American Tuberculosis Association, the American Association of Milk Commissions, the Society of the Alumni of Bellevue Hospital, a charter member of the Medical Association of the Greater City of New York, a life member of the Society for the Relief of Widows and Orphans of Medical Men, the Physicians' Mutual Aid Association, the American National Red Cross, the Association for the Protection of the Adirondacks, and the United States Navy League. He was an honorary member of the Jenkins Medical Society of Yonkers, the Queens-Nassau Medical Society, the Tri-State Medical Society, the Essex County Medical Society, and the Lehigh Valley Medical Association.

In 1881 Dr. Winters was married to Miss Annie Carnochan Ludlow, daughter of Thomas William Ludlow 3rd, Esq., of Yonkers, N. Y., and of Frances Fraser Bettner, his wife. His widow and an only child, Miss Mary Ray Winters, survive him.

OUR LATIN-AMERICAN LETTER.

(*From our own correspondent*)

Balboa Heights, C. Z., *December* 5, 1922.

MALARIA.

The Panama Canal is the mirror in which the American people reflects itself to its Latin brothers. Of course, the ships of all nations which transit the Canal and the citizens of all the world who traverse the strip of United States territory from ocean to ocean carry away with them some of the national ideals so wonderfully symbolized by the greatest engineering accomplishment of the human race, but it is upon Latin-America that the effect is greatest. The medical and sanitary phases of this gigantic undertaking have been widespread in their influence and a considerable proportion of the public health progress in the tropics of the Western Hemisphere is directly due to them. There was therefore a very genuine regret and some slight apprehension when a representative of a Panama Canal local of a trade's union was quoted by the New York *Times* of July 5 last to the effect that "the wonderful sanitation program which General Gorgas installed on the Canal Zone has been destroyed." Upon investigation this was not substantiated nor was the further statement that there existed "an epidemic of malaria and fever among Canal employees." Through the courtesy of Col. H. C. Fisher, Medical Corps, U. S. A., the Chief Health Officer, all data relative to the incidence of disease in the Canal Zone have been made available to your correspondent and, as is shown by the following table, malaria is not as prevalent among the employees of the Canal as it is in many parts of the United States; in fact, the rate for October, 1922, is the lowest for that month since 1918:

Malaria Incidence 1,0C0 Employees, The Panama Canal.

January, 1918—October, 1922.

Month	1918	1919	1920	1921	1922
January	2.53	2.95	2.62	1.52	1.08
February	2.54	3.57	1.51	1.21	1.29
March	2.03	4.34	1.57	1.19	0.56
April	2.24	1.66	0.22	0.37	0.28
May	1.86	2.72	0.36	0.72	1.65
June	1.50	3.53	2.44	1.69	1.96
July	1.66	7.04	1.97	1.89	2.21
August	1.93	3.15	2.75	1.87	1.65
September	0.98	2.06	2.31	1.13	2.03

November	1.51	1.48	1.25	0,88	*
December	3.40	2.00	1.17	1.37	*

*Data secured November 15, 1922.

During the calendar year, there has been an increase of malaria cases over previous years among Army and Navy personnel. This is accounted for by the fact that this class of Canal resident goes for military maneuvers into the endemic malaria areas adjacent to the Zone which is sanitated by the American government. Even among this class, the malaria noneffective rate is surprisingly low. The general health of the sanitated area continues to improve, in fact the death rate for 1921, 7.52 per thousand, was the lowest in the seventeen years of American occupation. No apprehension need therefore be felt by the outside world that the Panama Canal is in any way departing from the public health program which permitted its creation.

FOOT AND MOUTH DISEASE.

On account of the reported prevalence of foot and mouth disease in Jamaica, horses, mules, asses, cattle, sheep, swine, goats, chickens or any other domesticated fowls, hides or skins of any description, hay, grass, straw and goods packed in the same, have been prohibited entry into the Canal Zone or the cities of Colon or Panama, from Jamaica.

NARCOTIC DRUGS.

The Acting Governor of the Panama Canal, in a circular issued October 23, 1922, relative to the enforcement of the Narcotic Drugs Import and Export Act of May 26, 1922, states: "On account of the smuggling of narcotic drugs into the Canal Zone and Canal ports . . . take all possible precautions to cooperate with the authorities . . . in breaking up this pernicious traffic in habit forming drugs. From the number of cases of smuggling in which the crews of vessels have been implicated, it would appear that proper steps have not been taken by the masters of vessels to prevent such smuggling. Members of the crews who have been caught smuggling narcotic drugs or are known to be dealers in narcotic drugs should . . . not be brought to the Canal Zone either as members of the crews or passengers."

MEDICAL MEETING.

The monthly meeting of the Medical Association of the Isthmian Canal Zone which was held at Ancon Hospital on November 17, 1922, was devoted entirely to reports of surgical cases as follows: Granuloma Inguinale, C. D. Holmes, M. D.; Osteogenesis Imperfecta, T. C. Brewer, M. D.; Fibroid of Uterus with Severe Anemia, and Sarcoma of Mesentery, H. L. Krafft, M. D.; Acute Intestinal Obstruction, L. B. Morris, M. D.; Gallstones at Ampulla of Vater, Hydropyonethresis with Uretral Calculus, and Harelip, H. K. Tuttle, M. D.

ORTHOPEDIC CLINIC.

The Rotary Club of Panama with the cooperation of Major Edgar A. Bocock, M. C., U. S. A., is endeavoring to extend the scope and usefulness of the orthopedic clinic in connection with Santo Tomas Hospital. A ward of ten beds has been set aside by Major Bocock, the Superintendent of Santo Tomas, for the exclusive use of crippled children, and each of the sixty local Rotarians is to assist by discovering children needing orthopedic care and in bringing them to the hospital for examination and treatment. The local press will cooperate by giving publicity to the movement.

DIPHTHERIA.

In an endeavor to control and eradicate diphtheria from the city of Panama, R. P., Dr. Henry Goldthwaite, the City Health Officer, with the assistance of the Panama Canal Board of Health Laboratory, has been making cultures from the throats of all school children since August 14, 1922. The work is proceeding rapidly. Of the approximately 11,000 children of school age in the city, 7,450 had been examined up to November 20, 1922. In this group, 174 carriers of which thirty-eight or twenty-two per cent. were virulent, were found. This is a rate of twenty-three per thousand for the carriers and of five per thousand for virulent carriers. Virulent carriers are admitted to Santo Tomas Hospital immediately upon discovery and placed under appropriate treatment, tonsils and adenoids being removed and other nasopharyngeal foci being cleared up. The results have been most satisfactory to the Chief Health Officer of the Panama Canal under whose general direction all health work in the Canal Zone and the terminal cities of Colon and Panama is carried on.

SHIP FUMIGATION.

The Chief Quarantine Officer, Dr. W. C. Rucker, immediately upon his return from the United States instituted as a routine practice the use of cyanogen chloride in the fumigation of ships for the destruction of vermin.

OUR LONDON LETTER.

(*From our own Correspondent.*)

London, December 10, 1922.

HOLLANDER ON INSANITY.

Dr. Bernard Hollander, an authority in this country on mental disorders, said the other day that his extended and varied experience in the treatment of mental patients had convinced him that one of the most pressing needs of the community was to find the means of diminishing, if not actually preventing insanity, and that one of the steps in that direction was the early treatment of mental disorder, which is hindered by the present Lunacy Laws: 1. Facilities to treat suitable mental cases for a period not exceeding six months without "certification." He pointed out that it is a hardship that persons only slightly deranged and conscious of their condition should be forced against their will into asylums, where they form one of a crowd of patients, many much worse than themselves, and addicted to disgusting language and habits. 2. Greater facilities are needed for the organized study and research of insanity. 3. All institutions for mental patients, public and private, should be made open institutions by law; that is to say, in addition to the resident medical staff, visiting physicians should be appointed and have a certain number of patients allotted to them, the same as is the case in other diseases treated in general hospitals. According to Dr. Hollander this would do away with the frequent accusations of wrong detention and ill treatment, and would enable the one measure essential for the recovery of these patients, namely, individual treatment. Many asylums have one to two thousand patients and a staff of only three or four physicians. 4. There should be no more "licensed houses" which any man without any qualifications for the work can purchase as a business speculation. Licenses should be granted to "individuals" only, such as, by their training and experience, can be recommended for them.

A new Lunacy Act is about to be introduced into the House of Commons ere long. Reforms in this direction seem to be needed badly, very severe criticisms having been brought recently against the conduct of asylums generally. It is beginning to be recognized now that certain forms of mental disorder, if taken in time, can be cured, and that the treatment of a sick mind is analogous in some respects to that of a sick body; in fact, some forms of mental abberation—dementia præcox, for example—have been ascribed recently by well known alienists to a physical basis.

There is little doubt that mental hygiene, properly carried out, will prevent some cases of mental disorder from proceeding further; at any rate, mild cases should not be allowed to mix promiscuously with really bad cases. This is not the way to improve such cases, but to render them worse. Reforms are called for in the management and treatment of mental disorder in every country.

PASSING OF GOUT.

Sir William Wilcox recently drew attention to the fact that true gout is practically incurable. Indeed, few cases are now seen of old fashioned or classical gout and the modern tendency is to overlook it. One of the very best books written on gout is by Dr. R. L. Jones Llewlyn, published by Heineman of London. It deals with gout in all its manifestations, including its modern manifestations. With the writers of fifty or sixty or more years ago gout was one of the diseases most frequently mentioned. In the *Pickwick Papers* the following conversation is related to have taken place: "Well done, father," said Sam. "Take care, old fellow, or you will have a touch of your old complaint, the gout." "I've found a sov'rin cure for that, Sammy," said Mr. Weller, setting down the glass. "A sovereign cure for the gout," said Mr. Pickwick, hastily producing his notebook. "What is it?" "The gout, sir," replied Mr. Weller, "the gout is a complaint as arises from too much ease and comfort. If ever you're attacked with the gout, sir, just you marry a widder as hae got a good loud voice with a decent notion of using it, and you'll never have the gout again. It's a capital prescription, sir. I takes it reg'lar and I can warrant it to drive away an illness caused by too much jollity." Having imparted this valuable secret, Mr. Weller drained his glass once more, produced a labored wink, sighed deeply and slowly retired.

AMERICAN MILK SUPPLY.

Professor John Robertson, M. O. H., Birmingham, has returned recently from a visit to America, and on November 17 last, at a meeting of the Society of Medical Officers of Health held in London, read a paper on the American Milk Supply. Professor Robertson had visited the large towns of the New England states and the Central Bureau of Milk Control. He formed the opinion that the general milk supply was definitely better in America than in this country. It gave a certain assurance of clean conditions of production and of proper methods of distribution and handling. The American public could rely upon a milk which was richer in quality than that in this country, cleaner, of better keeping properties, and free from the risk of carrying infectious diseases or tuberculosis. The result of this had been that the American town dwellers had been induced to use an amount of milk much greater than the consumption in this country. Moreover, Professor Robertson pointed out that the improved American methods of dealing with surplus milk also tended to a lowering of the price. Although the price in America was nominally higher than in Great Britain, yet, when the purchasing power of the dollar was taken into consideration, it was, in effect, lower.

Book Reviews

TUBERCULOSIS.

Tuberculosis and the Community. By John B. Hawes, 2nd, M.D. Lea & Febiger, New York, 1922. Pp. 168.

This is a remarkable little volume, perhaps the first of its kind to treat tuberculosis distinctively in its social aspect. In the historical chapter one might find some serious omissions, but in view of the small size of the book this may be pardoned. However, since the author speaks of the German pioneers the omission of Dettweiler's name is unfortunate, particularly since in the early nineties of the last century he established the first sanatorium for the consumptive poor. In the same chapter there is an unfortunate printing mistake. In quoting Laennec's work the author uses the words "auscultation mediale" which would mean "middle auscultation," instead of "auscultation mediate." There is only one letter wrong but it makes quite a difference in the meaning. It is gratifying to see the beautiful tribute paid to Dr. Trudeau in this chapter and also to the pioneer work of Dr. Vincent Y. Bowditch.

In the chapter on the Frequency of Tuberculosis and the results obtained by the modern methods of combating the disease, the author is just a trifle too chauvinistic when speaking mainly of the results obtained in Massachusetts and omitting entirely the pioneer work which was done in New York long before Massachusetts followed the example of the campaign so successfully inaugurated by Dr. Hermann M. Biggs. The chapter dealing with the Cost of Tuberculosis is admirable and so are the two following ones on Hospitals and After Care. The value of Dispensaries is clearly set forth in Chapter 7. The chapter on Tuberculosis and the Nurses is divided into sub-chapters, the importance of each of which speaks for itself. They are: "The Training ing of the Tuberculosis Nurse," "Institutional Nursing," "The Field for the Public Health Nurse in Tuberculosis Nursing," "Details of Public Health Nursing in Tuberculosis," "Home Treatment," "Working Hours," "Salaries," "Records and Record Keeping," "Tuberculosis Surveys," "Clinics."

In the chapter on Tuberculosis and Its Relation to Schools nothing new is advanced, but at the end of it the author quotes Dr. F. P. Dressler's statement which appeared in the Bulletin of the U. S. Bureau of Education of 1912, as follows: "The normal with many of them is the abnormal. It seems more than foolish to shut up our well children in unventilated and improperly lighted rooms, furnish them no playgrounds, compel them to live a life not in accord with the laws of physical development and then when they become anemic, nearsighted or defective, make a great stir about special classes for defectives, and spend in building special schools money better spent in keeping children well . . ." The reviewer has repeated this strong statement because it shows the crux of the actual school situation in many cities of the United States. In the chapter on Tuberculosis and Housing the author quotes mainly from the work done in New York by Dr. Biggs, in France by Lagneau, and in Edinburgh by Williamson, which are familiar to all students of the social aspect of tuberculosis and bear out the oft-repeated maxim "Tuberculosis is a home and house disease."

In the chapter on "Tuberculosis and Occupation" periodical examinations and sanitation of workshops and factories and the selection of men and women making it possible to give men the kind of employment that they are physically adapted to engage in, is recommended. Chapter 12 deals with the Tuberculosis Programs in small Cities and Towns, and as an example he refers to the Community Health and Tuberculosis Demonstration in Framingham, Mass. In the chapter on Bovine Tuberculosis proper control is emphasized. Chapter 14 deals with the Incorrigible Consumptive, and here the author touches on official phthisiophobia and official phthisiophilia, and at the end of the chapter says: "For many years to come the problem of the 'incorrigible consumptive' will be a difficult and distressing one. Its solution means education of children, education of their parents, education of the medical profession, and education of legislators." The last chapter of this remarkably interesting little book is devoted to the methods of the tuberculosis campaign which are so familiar that they do not need recapitulation here. For anyone interested in the social aspect of tuberculosis no more instructive volume can be recommended.

PULMONARY TUBERCULOSIS.

Pulmonary Tuberculosis. By Maurice Fishberg, M.D. Third Edition, Revised and Enlarged. Illustrated With 129 Engravings and Twenty-eight Plates. Lea & Febiger, Philadelphia and New York, 1922. Pp. ix-891.

Dr. Fishberg's book has established itself so firmly as the authoritative textbook on pulmonary tuberculosis that the new edition is sure of a cordial welcome. It is a new edition in fact as well as in name, for the entire book has been reset, several chapters have been rewritten, notably the ones on phthisiogenesis and on artificial pneumothorax, and many new sections have been added.

It is refreshing to read a book that reflects the vivid and original personality of its author. The writer's fundamental knowledge of his subject is shown in the keen critical comments that appear on almost every page. The literature of tuberculosis is very completely represented, indeed this is one of the distinctive assets of the book, particularly because it has been critically selected and its discussion illuminated by the exposition of the personal experience of the author.

Dr. Fishberg does not hesitate to express heterodox views on many phases of the tuberculosis problem. On investigation, however, it is found that they are usually well supported by facts. It is interesting to note that a number of points of view which the author defended almost alone five years ago have become the common possession of tuberculosis specialists today.

The two new chapters on The Reciprocal Relations Between Pulmonary Tuberculosis and certain Physiological and Pathological Processes and on the Medical, Legal and Insurance Aspects of

Tuberculosis merit special mention. In the first of these the influence of tuberculous infection on growth, puberty, menstruation and a number of other physiological processes is ably discussed. The apparent antagonism between lymphatism and progressive tuberculous diseases is pointed out. The reciprocal relations between pulmonary tuberculosis and many other affections are well presented. The author's careful clinical observations appear in many passages. He reports, for instance, that nephrolithiasis and cholelithiasis are rare in tuberculous subjects.

In a chapter on the medical and insurance aspects of tuberculosis the author discusses the disability resulting from tuberculosis and points out that many tuberculous patients are able to pursue gainful occupations. The treatment of the subject of traumatic tuberculosis of the lungs is very complete and the discussion of the medical examination for life insurance is adequate and very timely.

Dr. Fishberg's work is one of the rare textbooks that is not a mere compilation of what others have written before, but one that represents the fruits of long experience of an able clinician, a master of his subject from both the theoretical and practical aspects, who possesses a clear and lucid style. It is a book that is indispensable not alone to the general practitioner but to the internist, tuberculosis specialist and public health worker as well.

JOURNALS ON TUBERCULOSIS.

The American Review of Tuberculosis, vol. vi., Nos. 3, 4 and 5. Journal of the National Tuberculosis Association, Allen K. Krause, Editor.

The numbers of *American Review of Tuberculosis* for May, June, and July, 1922, present such a wealth of information on tuberculosis science, that in order to do justice to the many excellent articles these numbers contain, one would have to write much more than can be contained in a review.

Because so much is claimed by European, particularly German investigators, for the results obtained by chemotherapy in tuberculosis, through the use of some arsenic and silver compounds, that the conclusions of Maurice I. Smith are highly interesting. They are in brief as follows:

1. Neoarsphenamine and silver arsphenamine have a very slight inhibiting action on the growth of the tubercle bacillus in vitro. Colloidal silver oxide has no effect whatever on its growth, while silver methylene blue has a very considerable inhibiting action on its growth.
2. None of these substances has any demonstrable effect on the pathogenicity of the tubercle bacillus when exposed to their action in vitro at body temperature for forty-eight hours.
3. None of these substances when administered to experimentally infected tuberculous guineapigs has any favorable influence on the course of the disease.

Dr. James Alexander Miller, in his presidential address, entitled The Power of the Spirit, pays a beautiful tribute to the founder of modern American phthisiotherapy, the immortal Edward Livingston Trudeau.

Haven Emerson's article describes the many causes which have led to the remarkable decrease in the deathrate from tuberculosis under the three principal headings:

First, Specific Measure: such as early physical diagnosis, bacteriological diagnosis, notification, segregation, ordinances against indiscriminate spitting, pasteurization of milk, etc. Second, under Accessory Factors, he mentions reduction of infant mortality, nutritional protection of children, open air classes, improved housing, and general education. Third, under Accidental Factors, he mentions limitation of immigration, war service by putting under favorable condition predisposed individuals between the ages of twenty-one to thirty-one, higher wages, shorter hours and better feeding, prohibition, undiscovered tuberculosis because of influenza, and favorable climate, 1920 to 1921. He concludes this highly instructive article by saying:

"We must expect a slackening in the rate of reduction as the effects of the influenza epidemic subside, but if employment on a good level of remuneration is reestablished, and the reaction against the Eighteenth Amendment subsides, there seems to be no good reason to doubt the continuance of a decline in tuberculosis mortality in this country at a rate at least as rapid as has prevailed for the past twenty years in the United States or in Massachusetts or in New York City."

Of intense historical interest is Dr. Krause's scholarly article on the Practice of Artificial Pneumothorax by the Hippocratic School. It only proves that there is nothing new under the sun and that even the great Forlanini and our own late Dr. Murphy, of Chicago, had their predecessors.

The first article is a report on findings in the chests of normal children by Pancoast, Batjaer, and Dunham, which is invaluable because it clears up many heretofore obscure points in the diagnosis of tuberculosis in childhood.

Dr. Knopf's article entitled A Physical Adjuvant in the Rest Cure of Pulmonary Tuberculosis, concludes the series of interesting contributions on modern tuberculosis science. A condemned report on the experiments described therein particularly intended for the general practitioner, appeared in the New York Medical Journal of July 19, 1922. Dr. Knopf's adjuvant has for its main purpose to add local rest of the lung to the general bodily rest for the tuberculous patient.

All three numbers of the *Review* contain the usual valuable abstracts from the current tuberculosis literature of Europe and United States.

TUBERCULOUS PERITONITIS.

Behandlung der tuberculosen Bauchfillerkrankungen in Kindesalter. (Sammlung von Verdauungs-und-Stoffwechselkrankheiten). Von H. Finkelstein und E. Rohr. Halle a.S: Carl Marhold Verlagsbuchhandlung, 1922.

Finkelstein and Rohr give a summary of their experiences with tuberculous peritonitis in children. Considerable ascites, which shows no tendency to subside, should be tapped. In adhesive peritonitis sun therapy combined with plenty of nourishment and good fresh air does a great deal of good. X ray therapy is also at times beneficial. Intestinal tuberculosis and the ulcerative form of tuberculous peritonitis are most resistant to every form of treatment.

MENTAL DEFICIENCY.

Mental Deficiency. By A. F. Tredgold, M.D., M.R.C.P., F.R.S., Ed. Fourth Edition. Revised and Enlarged. New York: William Wood & Co., 1922. Pp. xx-569.

This is the fourth edition of a work of extremely high order. An earnest effort is made for a better understanding and a more sensible classification and handling of the feebleminded. The manner of presentation is most lucid and this very simplicity makes it useful to the practitioner without detracting from its high scientific worth. Numerous new concepts, formulated by the author, which have appeared recently in various publications, have been included in this last edition. There is a profusion of case histories, photographs, and a number of ingenious diagrams throughout the work. The world's literature on amentia has been carefully gone over and included. One of Tredgold's most interesting suggestions is that of an international nomenclature dealing with various types of amentia. This is worthy of serious consideration. His scheme is a sensible one and some effort should be made to bring about a change such as he suggests.

DIAGNOSIS.

Lehrbuch Linischer Diagnostik und Unter suchungsmethodik fur Studierende, Medizinal praktikanten und Aerzte. Von Prof. Theodor Brugsch und Prof. Dr. Alfred Schittenhelm. Fifth Edition. Berlin and Vienna. 1921: Urban und Schwarzenberg.

The present volume comprises 968 pages and 418 text figures. In their preface the authors style the late war and reconstruction period "the Revolution." The work appeared originally in 1908, the third edition just before the war and the fourth in 1918. The size has undergone but little change since the first appearance of the work. The postbellum era has seen a reawakening of scientific ardor and the authors have given their readers the full benefits of electrocardiography and abdominal röntgenography. Other advances are in the application of micromethods to diseases of metabolism and a revision of the symptomatology and diagnosis of uterus. The Aschoff school is followed in dealing with tuberculosis.

PRACTICE OF MEDICINE.

A Text Book of the Practice of Medicine. By Various Authors. Edited by Frederick W. Price, M.D., F.R.S., Edin. Oxford Medical Publications. London: Henry Frowde and Hodder and Stoughton, 1922. Pp. 1753.

With the assistance of twenty-five authorities on the subjects with which they deal, Dr. Frederick W. Price, well known as a leading cardiologist, has produced a most able and valuable work, including sections on Diseases of the Skin and Psychological Medicine, and Tropical Diseases, in one volume. The book is intended for general practitioners and senior students, and for this reason is eminently practical, no place being found for history, and pathology is curtailed, while etiology, symptoms, diagnosis, prognosis and treatment are thoroughly considered; indeed, we know of no work of its size in which the last named has received so much attention. The book is divided into twenty sections, of which the first contains an excellent article on Fever by Dr. M. S. Pembrey, followed by the consideration of Infection, Immunity and Immune Therapy, by Sir Thomas Horder and Dr. John Matthews, to which we would particularly draw attention. Diseases of the Circulatory System, by the editor, with numerous figures of heart and pulse tracings, and those of the Respiratory System by Dr. R. A. Young and Dr. G. E. Beaumont, and of the Nervous System by Dr. James Collier and Dr. W. J. Adie, are invaluable, and if for these only the book would be well worth purchasing. Dr. C. R. Box's description of the Infectious Fevers is concise and to the point. In the section dealing with Diseases of Metabolism, Dr. George Graham writes on Diabetes, describing the method of treatment to which his name is usually gvien. Dr. A. F. Hurst is responsible for Diseases of the Digestive System; in some instances, perhaps, the treatment suggested is beyond the scope of general practice. Gaskell's classification has been adopted by Dr. W. Langdon Brown and Dr. Geoffrey Evans in their wellwritten articles on Diseases of the Kidneys. Sections 16 and 17, devoted to a consideration of the Diseases of the Joints, Fibrous Tissues and Muscles, and of the Bones, by Sir W. H. Willcox, are well described, and the same authority is naturally responsible for Diseases due to Chemical Agents. Diseases of the Skin by Dr. A. M. H. Gray, and Tropical Diseases, by Dr. G. C. Low, are well treated, and Psychological Medicine also is given full consideration. The book is easy to handle, and within its 1,753 pages a wonderful amount of information is contained. The editorial work has been well done, and the editor is heartily to be congratulated, both as regards his own part of the work and his choice of the contributors. We know of no book on medicine in one volume which can be compared to it, and it cannot be too highly recommended.

PHYSIOTHERAPY.

Manual of Physiotherapeutics. By Thomas Davey Luke, M.D., F.R.C.S. (Ed). New and Revised Edition. Wm. Heinemann Medical Books, Ltd.

Physiotherapeutics on the treatment of disease other than by drugs has come greatly into vogue during recent years, although even now it does not hold so prominent a place in the medical curriculum and practice of medicine as its importance deserves. As a matter of fact, on account of a lack of training in such methods, the ordinary medical practitioner has vague ideas as to when and how to apply them. Nowadays, the public require that the medical profession should be in touch and have some knowledge of every method of cure. In the volume before us the author deals with all therapeutic measures included under the term of physiotherapeutics, baths, massage, rest, electricity and diet. While the British health resorts are accorded a due meed of praise, the author warns against two classes of so-called hydropathic establishments, those which are to all intents and purposes quite ordinary boarding houses and those which although given the high sounding name of hydropathic establishments are no more nor less than pleasure resorts in which there are no facilities for treatment of any kind. Vibratory treatment is given high praise. The concluding part discusses briefly dietetic treatment and tea is considered a beverage only second in its injurious effects to alcohol. While the statement is somewhat of an exaggeration, many would regard coffee when taken in large quantities as more harmful than tea, there is little doubt that perhaps the majority of English people drink more tea than is good for their health. On the other hand, it is more than likely that Americans impair their digestive functions by imbibing too much coffee. The book is well bound, well printed and excellently well and adequately illustrated.

THERAPY.

Greundriss der Klinischen Therapie inner Krankheiten. Von Prof. Dr. Georg Klemperer. Berlin und Vienna: Urban & Schwarzenberg, 1922.

The author with whom Dr. L. Dunner has collaborated in getting out the present volume, divides his subject matter as follows: general treatment of the sick individual; infectious diseases; diseases of the digestive, respiratory, cardiovascular, renal, hemic, arthritic and nervous systems; and disorders of metabolism.

The author has for many years edited the periodical *Therapie der Gegenwart* and is one of the best known therapeutists in the world. An extensive formulary is appended.

MASSAGE.

Massage and Medical Gymnastics. By Dr. Emil A. G. Kleen and Various Contributors. Second Edition. Price $7.00. New York: William Wood & Co., 1921.

Kleen's original treatise on massage appeared in Swedish in 1890 and was promptly translated into German and English. In 1918 the work was brought up to date through the collaboration of Dr. Arvedson, Dr. Haglund, and Dr. Zander, and an English translation was made by Mina L. Dobbie. The second or present edition has been carefully revised by the translator. Dr. Kleen is still the responsible editor of the work, and finds that in the past two decades there have been but little to add to the teaching of massage. Dr. Arvedson contributes the section on Lung's medical gymnastics; Dr. Zander that on the Zander system of exercises, while Dr. Haglund writes of massage and gymnastics in orthopedics. Of the original editions up to 1918, 3,000 copies had been sold, and the present revision will doubtless meet with the same degree of success.

TROPICAL HYGIENE.

Aids to Tropical Hygiene. By Col. R. J. Blackham, C.B., C.M.G., M.D. Second Edition. New York: William Wood & Co., 1922. Pp. vi-240.

This compact little volume gives an extremely interesting résumé of the entire scope of tropical hygiene and public health service. Though it would seem from the technicality of its language to have been prepared with the professional student of tropical medicine or the public health officer in mind, it is not for that reason without interest and significance for the nonprofessional reader. The author admits that tropical and subtropical regions are unsuited to the more civilized races and assigns as the probable reason for the decline of the tropics, "originally the source of human culture," the spread of the socalled tropical diseases by multiplication of facilities for intercommunication, and first among these tropical diseases he places malaria, closely followed by the various other tropical fevers.

The discussion of soil and climate, air and water, food and clothing, the disposal of refuse and the disposal of the dead, treats in detail conditions as they exist and as they might be improved. The chapters on Water and Water Supplies, Insects, Arachnids and Rats, Animal Parasites, and particularly that on the Prevention of Malaria, are most illuminating and informative.

The work is valuable not only professionally to the student of hygiene and to public health officials, but is intellectually entertaining from its concise composition and smooth style in the discussion of sanitary matters. Col. Blackham's book should have an appreciative reception from American readers generally.

GOUT.

La Goutte et al Cure Hydro-minerale. Par le Professeur agrege. Maurice Loeper, et les Docteurs Flurin. Glenard, Joly, Paillard. Piatot et Pierra. Paris: L'Expansion Scientifique, 1921.

This brochure of 144 pages comprises seven essays. Loeper begins with uric and oxalic acid gout. Piatot discusses the articular, muscular and remalgiform symptoms of gout, Joly gouty phlebitis, Flurin gouty bronchitis, Pierra uterine congestion of the gouty, while Paillard and Glenard cover the hydromineral treatment of gout.

AMERICAN LITERATURE.

Erik Dorn. By Ben Hecht. New York and London: G. P. Putnam's Sons, 1921. Pp. 409.

Gargoyles. By Ben Hecht. New York: Boni & Liveright, 1922. Pp. 346.

Eric Dorn is a charming blend of realism impressionistically told and in the very impressionism we get a hint of the fantasy which prompts the behavior of the characters it brings to life. Hecht has done something that is likely to be little appreciated. He has sought motives that prompt the action of his characters. In his *Gargoyles,* his more powerful book, this is more apparent. Some will be disappointed by Hecht's writings at not being sufficiently shocked. Others will be too shocked to read very far. With these critics we shall not concern ourselves. We are mostly interested in what Hecht has done, not in depicting life, and even death for that matter, and yet his work is splendidly truthful here—but in his ability to find motives for the activities, compensations, inadequacies, adjustments and maladjustments of his characters.

To depict sorrow and joy, to tell about what is going on brilliantly is no longer enough. We have gone beyond this. We now want to know why—at least some of us—and Hecht has a tendency to seek the reason. With the advent of Henry James we found psychology intruding into fiction. Thoughts, the most minute ones, were chased from one person to another, back again to cause and effect, and off again. It was equivalent to the development of the experimental psychology of his day, perhaps it was even a little in advance of his day. Then Dostoievsky gave us his unrivaled subjective-objectified psychopathological fiction studies. He did much probing and searching, and made some exceedingly farsighted observations, many of them corroborated by most modern psychopathology.

Hecht attacks from a new angle. He takes the attitude of the modern psychopathologist and seeks causes. He is not always letter perfect in his deductions, but in many instances he comes near enough to the truth to make it uncomfortable for those readers who only want to be entertained. To those interested in the why of human behavior—and among physicians there should be some such—his works will find full favor, be read carefully and with profit.

In *Eric Dorn* a dazzling ray of light is turned on to the world of law and then flashed into the realm of newspaperdom. The chapter on the old man is an excellent portrayal of senescence. Then we have a study of an unsatisfied love life which has, as its twisted root, a fluctuating bisexuality with a final attempted return to a mother image. *Gargoyles* is more pretentious and more farreaching. The characters are multiplied and the interweavings are more complex. Mercilessly he flays the demivirgin and shows her in her true colors. Fearlessly he shows the cravings for power, for wealth, for achievement, for show, for pomp, for splendor, for fame, and then, as the days close on the futile life efforts, the beating of the empty drums is heard dimly in the distance. Layer after layer of false covering is removed.

Do not read Hecht if you are squeamish. Do not read him if you do not want to face truths. It is only by facing them that we can ever alter anything in the slightest degree. Somehow it seems that Hecht has told his story before we were strong enough, or adult enough to hear it and face it. For some of us he comes as a clear, driving wind, bringing us face to face with Nature as it is.

THE PHYSICIAN AND POETRY.

Collected Poems. By EDWIN ARLINGTON ROBINSON. New York: The MacMillan Company, 1921. Pp. xi-592.

Early Tudor Poetry. By JOHN M. BERDAN. Studies in Tudor Literature, 1485-1547. New York: The MacMillan Company, 1920.

Highland Light and Other Poems. By HENRY ADAMS BELLOWS. New York: The MacMillan Company, 1921. Pp. x-135.

Modern Russian Poetry. An Anthology. Chosen and Translated by BABETTE DEUTSCH and AVRAHM YARMOLINSKY. New York: Harcourt, Brace & Co., 1921. Pp. xix-179.

How much does the medical man need poetry? Many a physician will say scornfully: "Not at all." He is afraid of betraying himself, of opening some sentimental chink in his armor of complacence. Yet he will admit that the healthy man needs a varied diet. Why not variety in mental diet as well?

So we give you poetry of different qualities and climes; within the field a varied diet in itself. Something into which to dig the teeth, to help you explore now that you have leisure, the mysterious hinterland of literature that perhaps you have not thought of since college days. In *Early Tudor Poetry,* John M. Berdan has made a fascinating and readable study of the subject. He shows how the shift in pronunciation of English shortly after Chaucer's days threw the literary world off its balance for a time. Chaucer and his immediate followers became difficult to understand, even to read. The growth of Humanism in England sent writers groping after classic and medieval forms. There was no national tradition. Poetry wavered in transition from copied medievalism, influenced by the scholastic tradition, until towards the end of the reign of Henry the Eighth English poetry as we think of it began to be born. Yet without the Tudor introductory phase, so frequently overlooked, and if studied at all, gone into in very little detail, Elizabethan poetry, Shakespeare and his contemporaries, might have been far otherwise. In the course of six complete essays Berdan has outlined in masterly fashion the literary history of the Tudor period. And many rare examples of the writings of that day render the book still more pleasing.

"Modern Russian literature took its rise in the early nineteenth century. This was, more or less, the Russian counterpart of the Elizabethan Age." With these introductory words Babette Deutsch and Avrahm Yarmolinsky offer their anthology of *Modern Russian Poetry.* A century is covered, the elements of this poetry discussed, the general trends indicated. Then in chronological order follow excerpts from the works of Pushkin and his successors. The outline of personal history preceding each group of poems is at times a little flippant, but the characterizations are no doubt just, so many actual, clear cut pictures of personality or near personality. When it comes to the translations of the poems, our admiration is unbounded. A very remarkable piece of work has been done. To make a poetic rendering of a foreign lyric is in itself difficult enough but to preserve rhythm, quality and rhyme scheme is truly a feat. The picture brought out in English cadences in Tyutchev's As Ocean's Stream is well worth quoting:

As ocean's stream girdles the ball of earth,
  From circling seas of dream man's life emerges,
And as night moves in silence up the firth
  The secret tide around our mainland surges.

The voice of urgent waters softly sounds;
  The magic skiff uplifts white wings of wonder.
The tide swells swiftly and the white sail rounds,
  Where the blind waves in shoreless darkness thunder.

And the wide heavens, starred and luminous,
  Out of the deep in mystery aspire.
The strange abyss is burning under us;
  And we sail onward, and our wake is fire.

From the formal perfection of the classic school to the revolutionary imagists, the transition has been subtly recorded. The powerful Hymn to Fire, by Konstantin Balmont, slipping like the fire's melody from gentle theme to leaping harmony, now hushed to rhyme, now pulsing high in flaming colors, is a splendid example of the poetic instinct in both author and translator. The recent imagist school has its own force like that of our escaped prophets. The crude things of earth it moulds into pictures of sound, rhythm, thought, each tinged to life by the artist's emotion. All in all, a noteworthy collection of little known poetry, thus made accessible to English readers in thoroughly satisfactory translation.

American verse in 1921 must be credited with two distinct achievements. Henry Adams Bellows's slender volume *Highland Light and Other Poems,* shows deft mastery. There are beautiful lyrics, powerful moments as in Undrowned—a sense of reality in all his work. The sea, Icelandic sagas, travel, combine in the work of this American of the great waste.

In the *Collected Poems* of Edwin Arlington Robinson we have the substantial contribution of America's foremost poet. The book is a treasure trove; in it one can wander at will through drama, tragedy, through keenly appreciated bits of local life, through sentient beauty in every form. The book is impossible to describe. It is poetry, great poetry.

PSYCHOLOGY OF LITERATURE.

The Literature of Ecstasy. By Albert Mordell. New York: Boni & Liveright, New York, 1921.

The author contends that the quality of ecstasy makes poetry, whether in prose or in verse. He finds greater poetry in prose works. He summarizes his theory:

"Ecstasy, imagination, and the unconscious are all convertible and synonymous terms for the primary source of poetry. They are the fruitage of the turmoil of the soul, due to apparently forgotten memories in us of the emotional lives in all our ancestors."

Unfortunately Mr. Mordell is inspired by little ecstasy in his own utterances. In correct thesic form he defines his terms, adduces every extant definition of poetry, practically all of which furnish him with the opportunity of reiterating his battle cry: There is more poetic prose than verse. He proceeds to prove his point by the use of countless authors' names, some well chosen passages. He discusses the psychology of creative utterance, and triumphantly concludes:

". . . poetry . . . is an emotional spirit holding literature in suffusion instead of being a branch of literature . . . we find . . . most of the old definitions of poetry exclude a great deal of the world's best poetry, and include much that is not poetry."

We are duly edified!

THE MIND IN POETRY.

The Poetic Mind. By Frederick Clarke Prescott, Cornell University. New York: MacMillan Company, 1922. Pp. 308.

This effort of Prescott's to better know the workings of the mind which creates poetry has been met with criticism by certain reviewers. Thomas Jewell Craven in the *Dial* for July, 1922, seems to be a worthy representative of this tribe of bombastic assertive ones who know with accuracy a great deal that is not so. He states that "Professor Prescott's cardinal blunder arises from his misunderstanding of the intentions of scientific inquiry. He is continually asking *why* instead of *how*. Science is not called upon to *explain* anything; its purpose is the description and correlation of sense impressions—no more and no less—and the validity of its investigations depends upon its close adherence to mental processes which are observable." There is more of the like but let this suffice. What would science do if there were no "mental processes" to observe as the case would be in the reading of Mr. Craven's review? There is more, much more, including a fair amount of fear about things which can be explained which leads Craven to say, ". . . it is not necessary to explain why a man writes poetry." It may not suit his purpose but medical psychology demands this, in the same critical fashion that it demands to know the "how" and "why" of the workings of the mind of the psychotic. It is to be regretted that Mr. Thomas Jewell Craven's dictates will not be allowed to prevent our continuing to ask the question of "why." This Prescott has done and done admirably. Modern psychology has given him the implements and he has used them effectively. He has shown that unconscious processes which may be traced with scientific accuracy are responsible for poetic creations. The book is replete with stimulating examples of the parallel between the unconscious mechanisms employed in the dream, in wit and in poetry. It is to be regretted that such infantile attitudes are taken regarding so serious and valuable a book as Prescott's by reviewers who are "critical" at the expense of being creative. The book is a distinct addition to the work of modern psychopathology and should give more light to the field of literature.

SYDENHAM.

Selected Works of Thomas Sydenham, M.D., By John D. Comrie, M.A., BSc., M.D., F.R.C.P. Edin. New York: William Wood & Co., 1922.

A most careful selection of the works of Sydenham. Those interested in the progress and history of medicine will find this book fascinating reading. Sydenham was an original thinker and, as Rabelais, he described many new syndromes and disease entities. These are emphasized in the present volume.

ATTITUDE TOWARD DEATH.

Aspects of Death and Correlated Aspects of Life in Art, Epigram and Poetry. By Frederick Parkes Weber, M.A., M.D., F.R.C.P., F.S.A. Fourth Edition. With 146 Illustrations. London: T. Fisher Unwin, Ltd., 1922.

The fourth edition of a most remarkable survey of the literature and art dealing with the topic of death and the correlation aspects of life. Much material direct and symbolic is presented. As a reference textbook it is exceedingly valuable.

DOBELL.

The Clinical Method in the Study of Disease. By R. M. Wilson. With a biographical note on the life of Dr. Horace Dobell. London: Oxford Medical Publications, 1922.

This little brochure contains an appreciation of Dobell's life and work. The influence of Dobell is clearly shown. It is a refreshing bit of writing and should serve as a stimulus to the general practitioner.

SYMPTOMATOLOGY.

Klinische Symptomatologie innerer Krankheiten. Von Hofrat Prof. Dr. Norbert. Erster Band. Zweite Teil. Korperschmerzen (mit Ausnahme der Bauchschmerzen). Second Edition. Berlin and Vienna: Urban & Schwarzenberg, 1921.

The first edition of this volume appeared in 1919 and has already been translated into English. According to the preface there was but little to add to the first edition. The various localities subject to pains considered in the book are cardiac region, loins, musculature in general, bones, joints, and head. A great drawback in a book on painful affections and pain is the total absence of illustrations.

Practical Therapeutics

LIMITATIONS OF BRONCHOSCOPY AND ESOPHAGOSCOPY.

By Charles J. Imperatori, M. D.,
New York.

Endoscopic procedures on the upper respiratory tract and the esophagus have reached a stage of exactness and precision that they should be more frequently applied as an aid to diagnosis and treatment of these parts. The internist's examination by the usual methods and the radiographic findings may all be satisfactorily oriented by the visual findings *per tubam.*

Of course, the term endoscopic, is almost synonymous with the removal of foreign bodies from these parts. There is no intention of decrying this important phase of endoscopic work, which in all but few instances is life saving; still, a larger field for these methods is as an aid in diagnosis and in local treatment. There are some limitations to these procedures and they should be understood as well as the indications.

Technically there are few instances in which the larynx, trachea, larger bronchi and esophagus may not be thoroughly visualized. Practically many adult patients refuse to permit the examination, either through fear of the instrumentation—having heard through others or having experienced, previously, inexpert methods. Inadaptability and noncooperation hinder considerably and make it necessary to resort to general anesthesia.

INDICATIONS.

In order to discuss the limitations of these methods it is primarily necessary to understand what are the indications for their employment. The indications may be briefly summarized as follows:

1. In diagnosis and treatment of all diseases of the hypopharynx, larynx, trachea, bronchi and esophagus. Also the stomach.
2. In those diseases, such as abscess of the lung, bronchiectasis and possibly asthma, where medicaments may be applied directly to the smaller bronchi.
3. As a means of diagnosis of the cause of hoarseness in infants and young children.

As confirmatory in diagnosis of diseases of the esophagus and in the treatment of strictures, whether organic or functional.

Especially is this method of use in confirmation of malignant disease of either the larynx or esophagus, but particularly the latter and without resorting to biopsy.

Gastroscopy is easily accomplished but the interpretation of the findings is difficult. To quote Schindler (1): "Many disease conditions that heretofore have not been clinically diagnosticable can now be recognized and brought under rational treatment. Gastroscopy should always precede an exploratory laparotomy for diagnostic purposes."

Exactly what are the limitations of these procedures? The patient, under observation, his age, his intended cooperation, the part to be examined, the anesthesia to be employed, the anatomical or pathological obstacles to be encountered, the time necessary for the examination and the immediate and the remote after effects, must of necessity all receive careful consideration.

Ordinarily advanced arteriosclerosis, with aortic aneurism and a kyphosis of the cervical vertebra, are the only contraindications that should deter one from doing a peroral endoscopic instrumentation, other conditions permitting.

Foreign bodies in the lung tissue have been successfully removed by Jackson. However, this procedure, that is plunging in the lung tissue from the nearest approach through a bronchus, in my opinion, except in selected cases, had better be referred to the thoracic surgeon or left to encapsulate themselves. All foreign bodies that have entered by the *via naturalis* can except in rare instances be removed endoscopically, perorally.

DIAGNOSIS.

Diagnosis of conditions in the larynx, trachea, bronchi and esophagus is as exact as the experience of the endoscopist is large. It is mainly a matter of accustoming oneself to differentiating the physiological from the pathological.

Regarding the treatment of bronchiectatic conditions and asthma, in my experience, patients suffering from the latter disease will rarely permit repeated treatments and conditions of bronchiectasis have been so infrequent, that no definite conclusions can be given.

In lung abscess, the attempts that have been made to relieve this serious condition have not been as successful as anticipated. In chronic lung abscess, and these seem to be all tuberculous, although the tubercle bacillus is rarely found in the sputum, the treatment per bronchoscope, with suction and irrigation, as suggested by Yankauer, has not given the hoped for results. Postural drainage has been as successful as this treatment and without the added danger, theoretical or otherwise, of infecting new areas of the pulmonary tissue.

CONCLUSIONS.

The best results have been obtained in those abscesses, that were acute and particularly following the inspiration of some foreign substance and in which the treatment was instituted within a short time after the onset. In pneumonia and influenzal abscesses this method of treatment does not give such good results.

In conclusion, it might not be amiss to say that the occasional bronchoscopist will always find these methods difficult and nonconclusive and, in so far as the patient is concerned—dangerous.

Methods such as these require repeated application in order to master the technic and the frequent observance of the cavities under consideration, in order to differentiate the physiological from the pathological.

TRANSPLANTATION FOR THE CORRECTION OF DEPRESSED DEFORMITIES OF THE NOSE.

By William Wesley Carter, M. D., F. A. C. S.,
New York

Many years have passed since I first became interested in the use of bone and cartilage transplants in the correction of that class of nasal deformities due more or less exclusively to a loss of bone and cartilage of the framework of the nose, and therefore observations drawn from experience with methods which have been subjected to the test of time may be of some value.

These cases constitute a distinct class and the principles of treatment are definite and are founded upon the laws of mechanics which govern the construction of the arch; for the framework of the nose, which of course has all to do with the maintenance of the elevation of the organ, is an arch composed of an indefinite number of bone and cartilage segments so placed that they form a curved figure which is selfsustaining when supported only at its extremities. The septum, as a vertical support, contrary to the belief of many, is not necessary in order to preserve the elevation of the nasal bridge, though it does strengthen the arch and its upper edge where it is fitted in between the lateral cartilages, fulfills the very important function of the keystone of this structure. In operations on the nose this fact must be kept foremost in mind, for many a case of depressed deformity has resulted from the submucous operation owing to the destruction or displacement of this important keystone through the carelessness or inexperience of the operator.

As previously stated, to correct the deformity, the arch must be restored, and this, in order that the correction may be permanent and the physiological relations between the different tissues which go to make up the nose may be maintained, should be done by replacing the lost structures by the introduction of tissues identical with those lost, these should be taken from the patient's own body and placed in the nose as quickly as possible. While in transit from one part of the body to another, the transplant should be carefully protected, it should be kept warm (the warmth of the operating room is usually sufficient), it should come in contact with no antiseptic or other protoplasmic poison, and the greatest care should be exercised to protect in every way possible the inherent vitality of its cells. I never place my transplant in saline solution, but take the graft just as it comes from the rib and wrap it up in a piece of sterile gauze and put it safely aside until the nose has been prepared for its reception. There is no need of preparing the nose first as I have previously advised, in fact experience shows that there is a distinct advantage in placing the transplant before the blood has had time to clot in the subcutaneous sac which has been formed by the elevation of the tissues over the nose. This sac should never be irrigated before the introduction of the transplant, but if the hemorrhage is severe and too much blood accumulates in the sac, it may be squeezed out. After the splint has been applied, the pressure of this instrument will control the bleeding.

I have long since abandoned my external incision between the eye brows, for the reason that a slight scar results and the incision is not at the lowest point of the subcutaneous sac into which the transplant is placed, therefore drainage is not as easily secured. From time to time, however, there still come under my observation cases where, for some special reason, the external incision seems preferable; in these instances I still use it with great satisfaction. I believe that the chances of introducing infection through this external incision are greater than where the single intranasal incision is used. This last statement may be considered inaccurate by those who regard the nasal cavities as habitually filthy and the abiding place for all kinds of pathogenic bacteria. In fact I was once accused of inaccuracy and my ability to transplant bone successfully through an intranasal incision was questioned, though at the time I had on record a series of some twenty-five cases of successful transplantation by this method. The doubting Thomas, however, in this case was a man whose ideas had been formed from a few experiments on animals and whose personal clinical experience in the transplantation of bone had been far less than his voluminous writings on the subject would indicate.

In intranasal surgery there are two factors in favor of the surgeon the value of which should not be underestimated, namely; the antiseptic properties of the normal nasal secretions and the established local immunity of the tissues to the bacterial flora normally resident in the nasal cavities. Here laboratory experiments may not agree with clinical experience, but it is the latter which interests the practical surgeon and is of paramount importance in his work. The intranasal operation is far more difficult than the external, for in elevating the tissues over the nose, making the notch in the frontal bone and other procedures, and later introducing the transplant and adjusting it in its proper position, the surgeon is obliged to keep clearly in his mind's eye the anatomy of the parts and be guided almost entirely by the sense of touch. In order to do this operation skillfully and successfully one must have the proper instruments and he must be familiar with their dimensions, furthermore he must be able to determine at all times during the operation by the sense of touch their exact position and their relation to the fascial planes and all of the anatomical structures involved.

If the nasal depression is great, the subcutaneous dissection of the tissues must be extended on both sides of the nose for some distance over the cheeks in order to permit of the use of some of this tissue for the building up of the nose. In doing this one must be careful not to injure the lachrymal duct, the angular artery or the infraorbital vessels and nerve; the dissection should be superficial to these. In these cases it is sometimes necessary to use several strips of bone superimposed and it may also be necessary to support the lower end of the transplant by introducing a strut of bone in the lower edge of the septum; one end of this strut rests under the lower end of the transplant and the other end is supported by the nasal spine of the superior maxilla. It is far better, where a considerable amount of bone is needed, to use several strips rather than one of more bulky proportions, for the former are more easily nourished and osteogenesis is favored; furthermore, there is a minimum of absorption in the centre of the transplant which, being furthest removed from the circulation, always suffers more or less from a lack of nutrition; this is shown by a thin line of absorption in the x ray plate in the centre of all transplants that have been placed for six months or longer.

The positive value of the periosteum cannot be denied; the contrast in the vigor of growth between bare and periosteum covered transplants is well shown in a number of x ray plates taken of cases in which both had been used. In removing bone for transplantation, I always preserve the periosteum on the outer surface of the rib.

If infection occurs, a part or all of the transplant will be lost. If we succeed in controlling the infection shortly after it has become manifest, that portion of the bone which has been exposed to the infection will present a dendritic appearance, due to the localized areas of absorption, for every particle of bone that dies will be absorbed, usually in about six weeks. In some instances the bone may be absorbed in its entirety. This does not mean a complete failure of the operation, for the dead tissue is replaced by connective tissue which sometimes corrects the deformity in a perfectly satisfactory manner. Infection, however, in a bone transplantation case, is an accident always to be deeply regretted, for if any portion of the transplant is saved, it means at best a long convalescence. The situation can usually be cleared up at once if the transplant is removed as soon as the infection manifests itself, but we always hesitate to do this if there is any chance whatever of saving it.

I have had remarkably few infections, but I believe that they will occur from time to time in the practice of any man who does much of this work regardless of how careful he may be. It is the accidental introduction of a foreign strain of bacteria that is to be feared, more than those habitually resident in the nasal cavities though none are to be trusted, and rigid asepsis must be the watchword.

The presence of acute infections of any kind is, of course, a positive contraindication to operation, but the question often arises as to whether we should transplant bone in the presence of chronic sinus infections. Of course every effort should be made to cure or at least to control these before operation, but many of the cases which need bone transplantation badly would not be relieved by this operation if we waited until a chronic ethmoiditis was cured. Saddleback noses are likely to be accompanied by ethmoiditis and especially is this so if the deformity is of specific origin. Personally I am inclined to class the virulence of the chronic sinus infections with that of the other habitually present bacteria of the nose, which as we know is low. However this may be, I have, on several occasions, secured good results by transplanting bone where the patient was suffering from both ethmoiditis and atrophic rhinitis. The condition was treated, of course, beforehand, but it was not cured at the time of the operation. It seems to me that there is abundant proof that the tissues of the nose becomes immune to the old chronic infections.

Bone transplantation should never be attempted a short time after any other cutting operation in the nose, for failure is almost certain to result. No attempt should be made to transplant the bone until the first operation is completely healed.

Deformities due to syphilis constitute the most difficult class of cases with which we have to deal, not only on account of the degree of the deformity, but chiefly because we are here dealing with perverted metabolism, and a bone transplant is most sensitive to this. There is always present a large amount of scar tissue, poorly supplied with bloodvessels, which must be removed before we can hope for a bone transplant to survive in such an environment. The general condition, too, of the patient is generally bad. As I have discussed these cases in detail elsewhere, I will only say here that when operation is considered the patient's general health must be good, he must be free from all active manifestations of the disease, he must be Wassermann negative and the rib selected for transplantation must show at least no gross evidence of having been affected by the disease. These cases are tedious and require great patience on the part of both the surgeon and the patient. In properly selected cases the prognosis is good; some of my best results have been secured in the correction of deformities due to syphilis.

In conclusion, I will say that the transplantation of bone and cartilage is the only means yet devised by which the class of nasal deformities under consideration can be permanently corrected. The technic involved in this work is delicate and in order to secure good results it must be carried out with scientific accuracy in all of its details. It is my belief that a failure to master the technic on the part of some who have attempted this work accounts for their failures and for their belief that the bone is absorbed. The fault is with the operator and not with the method.

Bone when properly transplanted is not absorbed, but it continues to live and grow, its growth being regulated by the functional demands of the part.

2 West Sixty-seventh Street.

Resistance to Tuberculosis.—Harry Gauss (*Colorado Medicine*, June, 1922) advances a chemical theory of resistance. It has been observed that three per cent. carbon dioxide causes some inhibition of the growth of the tubercle bacillus in the test tube, and that fifteen per cent. is tuberculocidal. Tubercle bacilli will not grow in carbon dioxide free atmosphere. Cultures of the bacilli buried in the tissues of animals and permitted to acquire the carbon dioxide concentration of the body are inhibited in their growth, while other cultures similarly buried, except that the ingress of air is permitted, show no inhibition. The end products of metabolism of the tubercle bacillus inhibit automatically the growth of the organism that gives rise to them. This study indicates that the concentration of carbon dioxide found to inhibit the growth of the tubercle bacillus occurs normally in the human body, and that this concentration probably does inhibit the growth of the tubercle bacillus, thus establishing this factor as significant in the resistance to tuberculosis.

Abstracts from Current Literature

Treatment of Tuberculous Empyema.—C. A. Hedblom (*Surgery, Gynecology and Obstetrics,* April, 1920) gives the following results of treatment of tuberculous empyema:

1. Primary or idiopathic pleurisy with effusion, in a large proportion of cases, is probably tuberculous in nature.

2. A past history of pleurisy with effusion is common in cases of tuberculous empyema. In many cases the effusion is serous at the onset.

3. Tuberculous pleurisy may be primary, or it may be secondary to a pulmonary, peritoneal, or other tuberculous lesion.

4. The onset of a tuberculous effusion may be insidious or it may be sudden and associated with an acute and severe constitutional reaction. A mixed pleural infection due to the perforation of a tuberculous cavitation often runs an acute and rapidly fatal course.

5. Diagnosis of tuberculous empyema is made by demonstration of the bacilli in the exudate, by animal inoculation, or by examination of the sectioned pleura.

6. A sterile effusion is probably tuberculous. An infected effusion may be tuberculous.

7. Empyema following primary idiopathic pleurisy with effusion, or empyema of insidious onset, especially in the presence of a pulmonary or other tuberculous condition, is probably tuberculous.

8. Empyema may be tuberculous in spite of persistently negative findings over a long period of time.

9. In a closed pleural cavity a sterile effusion, whether serous or purulent, should not be treated by open drainage, except in the presence of an impending perforation of the chest wall.

10. Repeated aspiration of only part of the fluid present is indicated in cases of serous effusion producing definite dyspnea on exertion or symptoms of circulatory embarrassment.

11. The replacing of aspirated fluid by nitrogen or filtered air may be indicated in cases in which there are symptoms of active phthisis referable to the same side as the effusion.

12. A sterile purulent effusion should be treated as though it were serous if the lung expands when fluid is withdrawn. If the lung is fixed in a collapsed condition or if the effusion persistently recurs, an extrapleural plastic operation is indicated.

13. Effusion in a closed cavity showing a mixed infection should be treated by the closed method with antiseptic solution irrigation, or by open drainage; the open drainage is indicated especially in cases of severe infection associated with extensive pulmonary tuberculosis, making irrigation hazardous.

14. Tuberculous empyema with a large bronchial fistula should be drained by the open method.

15. A large tuberculous empyema with mixed infection from a previous drainage operation or from spontaneous perforation of the chest wall requires a plastic operation, preferably after treatment with Dakin's solution.

16. A plastic operation involving closure of a bronchus offers the only prospect of cure.

The Treatment of Brachial Plexus Injuries.—Alfred W. Adson (*Northwest Medicine,* February, 1922) says that injuries of the brachial plexus vary in severity from a slight disturbance to complete paralysis of one or more roots, the result of effusion of blood and synovial fluid, shoulder dislocation, fractures, gunshot and stab wounds, stretching of nerves, laceration, and evulsion of the roots. Treatment depends on the cause and degree of the injury. No one method, either medical or orthopedic, should be used as a panacea for all brachial plexus injuries. Since many of the injuries are slight and a fair degree of recovery takes place following massage and exercise, surgical treatment should not be too hastily instituted, but, when needed, should be used to free up constricted nerves and to bring about an end-to-end anastomosis of the severed fibres. Gunshot and stab wounds of the brachial plexus should be treated like peripheral nerve wounds in other parts of the body. Accompanying dislocations or fractures should not be neglected.

The Larynx in Pulmonary Tuberculosis.—James Crockett (*Clinical Journal,* March 29, 1922) sums up his paper by saying that tuberculosis of the lungs may manifest itself first in the larynx, and that the earliest signs of laryngeal disease are: 1. An anemia of the tissues of the larynx out of all proportion to the general condition of the patient. 2. Limited unilateral areas of hyperemia. 3. Unilateral congestion or edema (simple catarrh is symmetrical). 4. A filling up of the interarytenoid space, causing it to become convex instead of concave. This may become necrotic and ulcerated. 5. Unilateral encroachment of the cord by the ventricular band. 6. Loss of the pearllike whiteness and thickening of the cord. 7. Limitation of the mobility of one cord because of paresis of the muscles of tension or of abduction. The main difficulty is to differentiate tuberculosis from syphilis, and these points are noted: 1. Syphilis affects particularly the anterior surface, tuberculosis the margin of the epiglottis. 2. Syphilitic ulcers of the larynx are punched out and surrounded by a congested area; tuberculous ulcers are shallow and irregular. 3. Syphilis goes deep; tuberculosis goes wide. 4. Syphilis is more common on the anterior part of the larynx, tuberculosis on the posterior part. 5. Potassium iodide removes syphilitic lesions rapidly; it makes tuberculous lesions worse, rendering the parts more edematous. The Wassermann and tuberculin tests should always be resorted to in cases of doubt or difficulty.

Latent Pleural Empyema with Acute Peritoneal Symptoms.—W. Goldschmidt (*Wiener klinische Wochenschrift,* June 1, 1922) reports a rare case, in which a man fifty-nine years old, was admitted to the hospital suffering with marked acute peritoneal symptoms, such as abdominal rigidity, spasmodic compressive breathing, diffuse pain in the abdomen with a tender point to the right of the umbilicus, pulse frequency of 90 and normal temperature and obstinate obstipation, which had been present for several days. The acute onset began three hours before admission. A dullness on the right side of the thorax was disregarded because of the predominance of the abdominal symptoms. At operation, the findings were unconvincing and a perforation (which was the preoperative diagnosis) was not demonstrable; a condition resembling intestinal obstruction from kinking was found at the hepatic flexure and relieved, but the patient died one week later. The necropsy revealed a right sided pleural empyema with abundant thin pus and the thickening of the pleura indicated the existence of an old process. The right lung was completely atalectatic and there was also a bilateral diffuse suppurative bronchitis.

The remarkable feature of this case was the latent course of the empyema up to the time that it produced severe abdominal symptoms. Abdominal rigidity and even shock are known to occur in the pneumonias of children and in the pleuritides and empyemas of children and adults, but the occurrence of a symptomless pleural empyema resulting in the picture of perforative peritonitis is very rare. The abdominal symptoms became manifest before the abdomen was invaded and the reflex symptoms in the abdomen, produced by pleural and intercostal irritation, affected not only the abdominal wall, but also the colon and cecum.

Tuberculous Lesions of the Right and Left Lung.—Stivelman and Miller (*American Journal of the Medical Sciences,* July 1922) conclude from their study of 1,048 cases that in early tuberculosis the right side is affected twice as often as the left, but, as the disease progresses, there is a marked increase in the number of involvements of the left lung, so that, in the advanced stage of the disease, the right and the left lungs are equally involved numerically. Patients, with a predominating left lung involvement, are liable to run an active course more often than those with preponderating right side lesions. In early phthisis, the side of the lung involved has no definite relation to the general prognosis, but, in advanced phthisis, the prognosis is distinctly less favorable in those with preponderating lesions of the left lung. The presence of but one interlobar fissure, moderate atelectasis, and the evil effects of sinistracardia and retraction of the stomach are factors which contribute toward the greater gravity of left lung lesions as compared to the right.

Diaphragm Irregularities.—Ralph C. Matson (*American Journal of the Medical Sciences,* June, 1922) says that the assumption that tenting of diaphragm always diagnosticates pleurodiaphragmatic adhesions is unjustifiable.

Tentings of the diaphragm, frequently seen on plate and screen at the termination of the hilidiaphragm superfices with characteristics, which are associated with pseudoadhesions, are purely physical phenomena brought about by two factors: During inspiration the diminished elasticity or rigidity of the lower bronchial branches prevents descent of that area of the lung base in immediate relationship to the bronchus involved; thus a dimple effect is produced on the surface of the base of the lung. The diaphragm being molded to the base of the lung by a negative intrathoracic pressure is held by suction in the dimple producing a tented appearance.

Diaphragm irregularities of the pseudoadhesion type are commonly found during the course of acute and chronic respiratory infections. In acute respiratory infections with peribronchial infiltration involving the lower bronchial branches, the irregularity disappears with *restitutio ad integrum.* In chronic respiratory infections with consequent connective tissue, proliferative changes in the lower bronchial ramifications, the irregularity appears to be permanent in nature.

It is reasonable to suppose that should infiltrative or proliferative changes incident to infection not halt at a point in the bronchial tree proximal to its termination, but, instead, proceed to the pleura, then the diaphragm would become adherent and pseudoadhesion would be converted into a true adhesion.

Angiolymphe as a Curative Remedy in Tuberculosis.—A. V. Frisch (*Wiener klinische Wochenschrift,* June 15, 1922) reports upon the use of and excellent results from, a remedy consisting of extracts of ixia rosea, morea sinensis and orchis maculata; it contains glucoses and glucosides, but no mineral salts or alkaloids. An ampule contains 0.05 gm. of extract to two c.c. of water. This is injected intramuscularly every day or every second day for one to two weeks; after an interval of one to two weeks, another series of six to twelve injections is given. These injections are borne without reaction even in highly febrile and toxic cases. Most of the cases (twenty) selected for this treatment were those that showed only a slightly favorable prognosis. The production of too severe a general or local reaction need not be feared with this remedy.

While this treatment is not a panacea in hopeless cases, it nevertheless does not aggravate the disease process. Most of the febrile cases showed a gradual defervescence and the toxic symptoms, such as nightsweats and anorexia, soon disappeared; the cough and expectoration were diminished, as was also the number of tubercle bacilli in the sputum. There was a marked increase in weight, associated with a regression of the auscultatory signs and a marked improvement of the subjective symptoms.

Role of the Lymphatics and Lymph Glands in the Absorption of Foreign Articles and Tubercle Bacilli.—P. T. Herring and F. G. MacNaughton (*Lancet,* June 3, 1922) state that the lymphatics form a closed system of vessels lined by endothelium and that the term lymph should be restricted to the fluid within them. The tissue spaces are not directly continuous with the lymph capillaries and the tissue fluids are not necessarily the same as lymph. The lymphatics are especially concerned with the absorption and carriage of solid particles and of material insoluble in water. Soluble matter enters the blood capillaries directly. Fine solid particles are not distributed along the lymphatics, but their spreading results partly from mechanical causes, gravity and muscular contraction, and particularly with the aid of ameboid phagocytosis. Many solid particles eventually reach the lymphatics in the cytoplasm of cells which enter the lymphatics by diapedesis.

The phagocytes are arrested in the first lymph gland they encounter, and passing from the lymph sinuses of the gland into the cortex and medulla of the gland, they discharge their burden among the lymphocytes located there. Solid particles, and even free erythrocytes, are taken up by the endothelial cells of the reticulum of the lymph sinuses which ingest the material, detach themselves, and carry it into the glandular lymphoid tissue in the same way. The lymph gland is an efficient filter and only allows solid particles to pass through it when they are excessive, or when the gland is disorganized. The lymphatics of the lymphoid tissue act as mechanical barriers, preventing the escape of the particles, and finally the barrier is reenforced by fibroblasts and the formation of fibrous tissue. The foreign material is surrounded, while the lymph sinuses are left unobstructed for the passage of lymph.

The tubercle bacillus undergoes the same fate as foreign bodies and are in addition acted upon by a normal physiologic process for the absorption and arrest of the bacilli. In the first lymph gland entered, some of the bacilli are destroyed, while others remain viable and produce a tuberculous focus in the gland. The resulting toxins induce an intense lymphocytosis in the other glands through which the lymph passes and render the glands less pervious to the bacilli by filling the lymph sinuses with lymphocytes. This protection is a mechanical one and the imprisoned organisms remain a source of further infection when the fibrous tissue and the protective barrier break down. These observations support Cohnheim's law that the tubercle bacillus reveals its site of entry in the body by producing characteristic changes in the lymph glands draining the site of entry. There is no evidence of a new formation of lymph glands in tuberculosis. Microscopic glands become enlarged, but much of the tissue associated with tuberculous glands is merely tuberculous tissue with a superficial resemblance to lymph glands.

Letters to the Editor.

A WORD TO CONSULTANTS.

New York, *December* 1, 1922.

To the Editors:

For many years I have thought what a model consultant the late Dr. Austin Flint, Sr., was. He would say with his genial, considerate manner, "Doctor, tell me about your case." After he heard your story in a room where you and he were alone, he would go into the patient's room with you. He would question and examine the patient as much as he thought necessary or desirable, and would then, with a kindly, helpful word, retire to the adjoining room with you. There he would go over the case with you and say frankly, if he differed with you as to the diagnosis or treatment. He would finally say, "Doctor, subject to your approval, I would suggest that you try later, or now, the use of such a drug or mixture." After leaving the room, one of the family of the patient would ask Dr. Flint what he thought about the patient or what treatment he advised. With a smile he would answer, very pleasantly, "Dr. Robinson is the attending physician. He will tell you and do everything required." With that he would bow and leave the house, with a good day.

Have I known other consultants to act in a similar, commendable manner? I have not. Usually they talk with one or other member of the family and say what they think or feel. Their words are frequently misinterpreted and hence cause trouble in lessening faith in the practitioner.

As a rule, and Dr. Flint knew it, the practitioner knows his patient and family far better than the consultant can know them. Hence, his advice is in reality more valuable. Occasionally the consultant's advice, or his diagnosis, is important and valuable. But this is not invariably true. Far from it. Therefore, the consultant should conduct himself in a fitting manner; namely, with due regard to amenities and to professional ethics, in the best sense. *"Verbum sat sapienti."*

PROFESSIONAL SECRECY.

New York, *December* 12, 1922.

To the Editors:

Personally, I am of opinion that all knowledge obtained by the family physician in his professional relations with his patients should be kept inviolate in all cases, when to reveal it in court and to the public in this manner is most reprehensible and should not be permitted by judges, except where criminality affecting the people's welfare is directly affected. Therefore, I am absolutely opposed to physicians stating in court, as to illicit relations between the sexes, as to the existence of venereal or malignant disease, in the case of the patient, of abortion, caused by ignorant or foolish doing. There are also other cases in which the doctor should be absolved from making a statement, or even answering a direct question of the prosecuting lawyer. In cases where criminality is involved, then if the judge decides that the doctor must answer clearly and sufficiently, his moral allegiance to his patient is covered and he is not bound by any sense of professional correct doing, if he responds frankly and completely, so far as he knows.

Beverley Robinson, M. D.
129 East Thirty-fifth Street.

Rochester, Minn., *December* 6, 1922.

To the Editors:

I am endeavoring to make a complete study of the distribution of human actinomycosis in this country. The number of cases reported in the literature is surprisingly small, and I know that the disease is not so rare as is sometimes thought. I shall greatly appreciate hearing directly from any one who has had experience with this disease, and desire to know concerning case histories the following: age, sex, occupation, residence, state in which the disease was contracted, location of lesion, duration of symptoms, and any special points of interest connected with the treatment, outcome of the disease, or necropsy findings.

PHILADELPHIA AWARD.

PHILADELPHIA, *December* 13, 1922.

To the Editors:

I enclose copy of a statement of the qualifications of Dr. Sajous for receiving "the Philadelphia Award." This Award is a sum of money to be given each year by a prominent citizen, to a citizen who fulfills certain requirements specified, to the effect that he or she has made the largest contribution to the welfare and good fame of the city. Last year—the first instance of the awarding—it was bestowed upon Leopold Stokowski, leader of the Philadelphia Orchestra. This decision was reached by a committee formed—so far as I know—largely by choice of the donor, Edward Bok.

Such a decision failed to command the enthusiasm of those of us whose complexes react to such broader issues as those of human welfare in the large.

I am offering a copy of this statement to the *Saturday Evening Post,* but have no expectation it will be accepted. In any event I hope the copy submitted to you may be found available and published promptly in order to meet the eyes of physicians and elicit expressions of opinion from them. If this award is not made to Dr. Sajous this year it might be some other year.

MADISON TAYLOR.

A CANDIDATE FOR THE PHILADELPHIA AWARD.

By J. Madison Taylor, A. B., M.D.

Professor of Physical Therapeutics and Dietetics, Medical Department, Temple University, Philadelphia, Pa.

If the purpose which animates the donor of the Philadelphia award is that the recipient shall be one who distinguishes the City as a center of world influence of both humanitarianism and scientific research and power, as well as one who fulfills the local conditions, I would name a man who fulfills all these requirements, but whose position and whose modesty may not seize and hold popular attention, or sentimentalities, nor arouse emotional reactions. That man is Charles Euchariste de Medici Sajous. He has lived here since early manhood, has done a colossal work, quite as much international as local.

His efforts as serving suffering and imperiled human beings have been one uninterrupted continuance of monumental force and success which will be more recognized generations hence, and even now is abundantly recognized by those who have the vision to see the obvious when amply demonstrated and verified.

The nature, character and scope of these achievements cannot be recounted here. They are written large on the tablets of fame; they include the whole field of life saving measures as these are displayed through the arts and sciences of medicine, private and public.

It is true Philadelphia made the discovery long after the world had done so and is only now coming to a realization of facts abundantly established in Europe, Asia, Africa, North and South America, and the Islands of the Sea. Testimony to that effect is readily available by any one whose vision is not restricted or who decides through reason, demonstration, and not emotion.

The local service, distinction or benefit rendered by this one man include—among manifold others—a scientific and practical presentation which compelled attention to the fundamental needs of furnishing solutions to a multitude of obscure problems which had heretofore retarded knowledge.

Whereas human beings subjected to the perils of disease of all sorts, kinds and degrees, had been furnished consisting of a vast accumulation of scientific findings competent to relieve suffering and save life, these findings were so detached, inadequately related, so unsystematic, so lacking in proportionate values and consistency, they often failed to produce such practical results as were well within their powers. There was lacking—before the appearance of the epoch making volumes of *The Internal Secretions* and *The Principles of Medicine* by Sajous in 1903—a centralizing thought or coordinating principle, or system of integration.

This coordination of the inchoate masses of information was furnished by Sajous in his painstaking researches, his judicial observations, his many genuine discoveries—some of new and essential facts—but more of a wide, judicial survey and sifting of testimony from which emerged just that reconciliation and illumination so urgently needed to vitalize and render available and for the practical application of the already existent findings.

Nay more; of course there was opposition, depreciation, misinterpretation, all sorts and kinds of retardation—as invariably follows a burst of explanation on new and unfamiliar lines. A lesser man—like many other heroes and prophets—would have been swept into oblivion, or only have achieved credit and acceptance centuries after his death.

Just here is where Philadelphia should come in. In spite of all the inevitable flood of opposition, so calmly and patiently and serenely did Dr. Sajous work and meet all attacks with perfect preparedness and unimpeachable proofs—long foreseen—and always from the vantage point of Philadelphia, that, in strong contrast to the fully expressed expectation and firm opinions of his friends, he not only justified and proved all his points, but led his opponents to admit him right, to accept his views in a few short years, at least while he is yet alive. His years, however, are now many and any award is more agreeable when one survives to receive it.

This influence generated in, evolved in, and grew to international proportions and advantage for world wide welfare, right here in Philadelphia. Not in one year, of course; no exploit of such cosmic magnitude could evolve in one year. No exploit, no service that any one could achieve in any one or two or fifty years compares with this.

Is Philadelphia, or the commission of the Philadelphia award, to overlook such distinction for Philadelphia—simply because it is so huge as to confuse vision?

Migratory Tumors of the Abdomen*

By ASA W. COLLINS, M.D., F.A.C.S.,

San Francisco.

The existence of migratory tumors of the abdomen not infrequently receives general mention in articles dealing with other conditions, which appear in periodical literature. Case reports, however, are curiously few, and standard textbooks covering the subject of abdominal tumors are almost uniformly silent concerning socalled aberrant or wandering types of neoplasms. In a work as extensive as that of Hertzler (8) we find nothing more definite than the remark that torsion of the pedicle or thrombosis may occlude the nutrient vessels of a uterine tumor so that "it may acquire a new attachment to an adjacent part, usually the omentum. These new attachments may supply the needed nutriment and the tumor may become entirely separated from the uterus and retain its attachment to its new host." Hertzler calls this process sequestration. Bland-Sutton (1), in connection with torsion of the pedicle of an ovarian or uterine cyst, mentions the possibility of the pedicle breaking so that "the tumor becomes detached from its uterine connections." He also mentions a case where "a dermoid which had undergone axial rotation so lengthened its pedicle that the tumor sometimes rested in the loin and resembled a very movable kidney; it produced no pain but annoyed the patient by its excursions about the belly." He also says that "in a small (uterine) fibroid with a thin pedicle, torsion will sometimes lead to its complete separation; indeed, a small fibroid detached in this way has been seen free in the pelvis. A subserous fibroid the size of a cricket-ball has been found completely detached from the uterus and adherent to the omentum."

Nicholas Senn (11) quotes Virchow, as an authority that it is "questionable" whether pediculated subserous tumors ever become completely detached, but says he himself "is satisfied that such an occurrence is possible, as in making a laparotomy for the removal of multiple myofibromata, he found in the abdominal cavity a detached tumor as large as a small pear."

That migratory tumors occur more frequently than these brief references would lead one uninformed upon the subject to suppose, is abundantly evidenced by a search of the literature. Van Buren Knott (10), reviewing the literature in 1905, gave the earliest reported case as that of West in 1858, who found a fibroid the size of a walnut in Douglas's cul de sac, supported by a "false membrane between the uterus and the rectum." Knott also quotes Roger Williams as mentioning a number of cases reported by different observers before 1880. I have not been able to verify these references.

The earliest case report which I have found is one recorded by William Turner (18), the specimen from which he exhibited to the Obstetrical Society of Edinburgh on December 12, 1860. Autopsy upon his patient revealed that the left ovary had become detached and was present as a large tumor adherent to the depending margin of the omentum, and to "the peritoneum covering the anterior surfaces of the bodies of the last lumbar and first sacral vertebræ." The right ovary and tube were normal, but "a calcareofibroid tumor about the size of a walnut" was attached to the uterus by a pedicle; "a roundish tumor about the size of a hazelnut" lay on the floor of the rectovaginal pouch, which was of calcareofibroid structure and "quite loose, having no connection whatever to the adjacent parts"; while "a third tumor of the same character, and of the size of a pea, was embedded in adhesions on the floor of the rectovaginal fossa." The author ventures the opinion that "it is probable that these tumors had at one time been connected to the uterine walls, and that they afforded examples of detached subperitoneal fibrous growths."

The famous obstetrician, Sir James Young Simpson (14), writing in 1871, mentions that he has several times seen detached tumors in the abdomen but gives no details. F. S. Porter (12) showed a specimen of a fibroid found unattached in the abdomen, to the Dublin Obstetrical Society in December, 1875. He "had not heard or read of any similar case."

J. Knowsley Thornton (17), an English surgeon, on April 2, 1881, removed from a patient who had been under his personal observation for nine years, a dermoid tumor which he found adherent to the omentum on the right side. This turned out to be the left ovary which appeared to have been detached and wandered to the right side. This hypothesis was confirmed by earlier notes made on the same patient, as he had palpated a small tumor on the left side many years before, and on examination one year prior to operation had found that the tumor was enlarged and moved over to the right side.

Malins (11) reports five cases "where cysts were transplanted to a new situation; in one the separation was not absolutely complete when the patient was operated upon, though the transplantation was advanced; in the three others the union from the place of original development was entirely severed, and a connection established under different auspices with fresh structures." Malins further remarks that "the process by which this (migration) was accomplished created much disturbance for a time, but the cysts afterwards appear to have settled down with a singular accommodation on the part of their surroundings."

In Heywood Smith's (15) case, a tumor about the size of an orange was found on the right side, adherent to the omentum and the oviduct, when freed from these the tumor "came away without a pedicle." No appendages were found on the left side but the right ovary and oviduct were found to be deep down in the pelvis on the right. The writer considers this migration of the ovary containing the dermoid cyst to be unique, but Halban (7), thirty-two years later, reported one very similar to it.

I. S. Stone (16) had two cases of "wandering, parasitic or aberrant retroperitoneal uterine fibromata" where the neoplasms had "succeeded in getting away from the uterus and even the broad ligament" escaping into the space below the peritoneum and there supporting an independent existence "remote from their former bed in the organ from which they sprung." The trend of the discussion which followed the presentation of Stone's paper would seem to indicate that most of his audience did not believe in the possibility of migratory tumors; one hearer saying frankly that he "should think cases such as reported by Dr. Stone are very, very rare."

The description of Croom's three cases is very interesting. In the first one "a tumor the size of a small cocoanut was found occupying the pouch of Douglas. On opening the abdomen and passing my hand into the pouch of Douglas, the tumor slipped up into the abdomen. It was quite free of any adhesions, and I was able to lift it out entire without securing or ligaturing anything whatever. I found no trace of any pedicle, and there was no hemorrhage whatever." In the second case "the tumor was adherent to the anterior wall, and on being separated and removed entire, it was found that the pedicle was not only twisted and very small, but had given way close to the neoplasm. Evidently this separation had taken place some time previous to operation, because the pedicle was dry and firm, and there was no indication of hemorrhage."

The third case Croom designates as a "curiosity." On opening the abdomen and "exposing and tapping the tumor, one slight adhesion to the abdominal wall was secured with catgut, and thereafter the tumor was simply pulled out of the abdomen, there being no further adhesion, and no apparent attachment to any pelvic or abdominal organ. The tumor was not ovarian because both the ovaries were intact. It is remarkable that a tumor of such size should have maintained an independent existence in the abdominal cavity with only a slight adhesion to the abdominal wall."

The first attempt at a review of the literature I find in Van Buren Knott's (10) paper published in 1905. From personal communications he collected two cases each from J. Whitridge Williams, F. H. Martin and J. M. Baldy. Those of Williams and Martin were myomata which had formed vascular connections with other structures before breaking away from the uterus, but in both of Baldy's cases a small detached tumor was found perfectly free among the intestines. Knott also reported two personal cases of fibromyomata unattached to the uterus, but obtaining nourishment by adhesions to the peritoneum and mesocolon.

A brief review of German cases of migratory ovarian tumor was recently published by Kayser (9) who also reports a case similar to those mentioned in the earlier literature.

Of Goullioud's (6) two cases, the first was an ovarian cyst which had become detached from its original site and at operation was found firmly adherent to the anterior surface of the uterus; the second was a uterine fibroid which was completely severed from its point of origin and was "isolated in the peritoneal cavity." The uterus was almost obliterated by another huge fibroid which was firmly adherent.

In the cases heretofore noted the patients were all women, the tumors having their origin in either the uterus or ovary. A case unique in many respects is described by Campbell and Ower (3) whose patient was a man aged sixty-nine. For a period of twenty-five years this man had been conscious of a mass in the right side of the abdomen, at first smaller than a hen's egg. It was originally noticed in the right hypochondrium, but was freely movable and would sometimes disappear into the pelvis for several days at a time. During the last six years it had increased in size, but was not tender and was dull on percussion. The patient came under observation because of a cystitis with retention due to hypertrophy of the prostate, and was so anxious that something be done for the abdominal condition that although the state of his kidneys rendered him a poor operative risk, laparotomy was undertaken. On cutting through the peritoneum the tumor showed a pearly white glistening surface, exactly comparable to a uterine fibroid. It had absolutely no pedicle nor any attachment whatever. It bore no apparent relation to any viscus, nor was there an adhesion of any kind attached to it. Indeed, on searching the abdomen there did not seem to be any adhesions present. On section the mass cut with some difficulty and seemed to have a calcareous centre around which the tissue was a little less hard than that of the remaining portion. No vessels, cells, nuclei, or fibrils could be demonstrated in the tissue. Although "the wound remained normal" and "the patient did well for the next seven or eight days," he and his tumor appear to have been intimately associated for so long, as to be unable to withstand the shock of separation. At any rate, the patient died on the forty-eighth day, and at autopsy a small subperitoneal calcareous nodule was found in a fibrous adhesion between the transverse colon and the under surface of the left side of the diaphragm, and a similar mass, white and calcified with a smooth surface under glistening peritoneum, was found in the small bowel about six inches above the ileocecal valve. The author's hypothesis is that the aberrant tumor had its origin in a similar calcareous mass which had new layers added to it from the surrounding envelope of peritoneum.

It will be noted that in none of the cases of migratory abdominal tumors which have been reported is there any mention of previous operation, or of the possibility of this peculiar type of neoplasm appearing as a graft from some earlier growth removed from the same patient. That such migration and reimplantation may occur, however, seems in every way probable. Last fall Brewer (2), of New York, reported a typical fibromyoma of the abdominal wall which developed ten years after hysterectomy, the uterus having been the seat of multiple growths of the same character. Brewer is of the opinion that this fibromyomata "arose from the implantation in the line of incision, of a minute fragment of the uterine tumor removed ten years before," because of the following circumstances: "First, the coincidence of the development of this tumor in an individual who had previously harbored an exactly similar growth in a neighboring structure; second, that in its removal the tumor bearing organ with its divided and exposed tissues had been for some time in actual physical contact with the divided and exposed tissues of the abdominal wall, in the exact location in which the secondary growth subsequently developed; third, the wellknown and generally recognized fact that certain cutaneous and mucous membrane tumors which are in close or frequent contact with neighboring tissues, not infrequently give rise to similar growths in the tissue thus exposed; fourth, that modern experimental surgery has furnished innumerable examples of successful grafts of tumor tissue as well as normal glandular structures, in both animals and man; and fifth, that surgical literature records not a few examples of both benign and malignant tumors arising in the immediate neighborhood of incisions previously made for the removal of histologically similar growths; as well as tumors developing from the accidental implantation of aberrant fragments of normal tissues or cells into a new and histologically different environment."

Concrete examples of such implantation are mentioned by Cullen (5) in writing concerning adenomyomas, and it seems reasonable to believe that other neoplastic forms might originate in the same way.

In considering this subject it is necessary to differentiate between migration and metastasis. By migratory, aberrant or wandering tumors, are meant those which originally arising in connection with some organ, nearly always the ovary or uterus, by some combination of circumstances become detached from their primary implantation. This ordinarily occurs only after the growth has formed adhesions with some other structure than the one in connection with which it originally arose, but not infrequently these masses have been found free in the abdominal cavity with no apparent source of nourishment.

The power of metastasis, on the other hand, is possessed only by those tumors which are of the infiltrating type, their component cells being able to pass out into the interstices of the connective tissue like the roots of a plant into the soil. Thus, cells growing from the periphery of malignant tumors invade the surrounding connective tissue spaces, or escape to greater distances—as into the lymph vessels and glands—where they proliferate, or they may even invade the blood stream and thus be carried to remote parts of the body (8).

Aberrant tumors must, therefore, be of what Hertzler terms the *expansile* type, that is, possessing the power of autonomous growth, but not of invading the surrounding tissue. They can, however, displace the tissue, and in this way form a socalled capsule which encloses them and from which they can be readily shelled out.

The infiltrating type forms no capsule, the cells extending from the mother tumor into the surrounding tissue, which with its contained vessels and nerve becomes a part of the tumor or is destroyed. Senn (13) says that the recurrence of a benign tumor is always local, and is invariably the result of incomplete removal of the tumor.

The exact cause of migration is rather obscure. The most common explanation, as we have seen in reviewing the literature, is that the pedicle of a neoplasm, usually a cyst or fibroid, is severed because of torsion or other cause of destruction, and, the neoplasm having previously formed adhesions with other structures than the one upon which it originated, continues an independent existence. This hypothesis does not, however, cover such cases as those of Baldy or the one described by Campbell and Ower. A tendency to isolation seems to be almost a law of the growth of uterine fibroids. If they are found within the uterine wall, the surrounding tissues often lie in such a way as to give an appearance of encapsulation; if they lie outside the uterine cavity they show a marked disposition to project into the abdominal cavity, developing a pedicle, and often becoming entirely detached. In the same way a fibroid, or a cyst upon the peritoneal surface, will project into the pelvic cavity, forming pedicles in the same manner as the intrauterine variety, and may later be severed from their original point of contact, either with or without having previously formed attachments to surrounding organs.

Should an encysted ovary, or a uterine leiomyoma contract adhesions with the surrounding parts, separation is, of course, much more likely to take place especially if it becomes attached to the bladder or colon, or any organ constantly undergoing changes in size and position, as the alternate contraction and expansion would, of course, exercise traction upon the pedicle of the tumor, so that it would stretch, and eventually give way altogether. Pregnancy might very well have the same effect, and if the tumor attained a large size, its own weight might add to the tension upon the original attachment.

All the clinical manifestations which have been evidenced by aberrant tumors of the abdomen may arise from the presence of ecchinococcus cysts, but hydatid disease is so rare on this continent that the chance of such cysts being found is very slight indeed, though the possibility of its occurrence should be borne in mind in all cases of obscure tumors among foreigners, especially those from Iceland, Australia, or southern and eastern Europe.

It is manifestly difficult, if not impossible, to make a positive preoperative diagnosis of a migratory tumor of any description. The existence of uterine fibroids, or of an encysted ovary, may well excite suspicion of such a possibility, but a more exact diagnosis than that of Thornton, almost forty years ago, is not likely to be made until a laparotomy has enabled the surgeon to recognize the true state of affairs.

Case I.—Mrs. E. C., married, aged forty-four, admitted March 4, 1917, mother of two children, youngest twenty years of age, has complained for past year of hemorrhages from the vagina at irregular intervals and pain in the abdomen. Examination (bimanual) showed a mass of irregular shape about the size of a large grape fruit occupying the region of the uterus. Operation March 6, 1917, hysteromyomectomy. The uterus contained many tumors of various sizes. Examination of specimen showed it had a semicystic consistency and on being incised the whole of the fundus of the uterus is found infiltrated by a soft mass which infiltrated the body of the uterus. This area measured one and a half inches in diameter. This area was very soft and differentiated itself from the surrounding tissue by being yellowish-reddish gray while the surrounding muscular tissue was grayish white. The mucosa was velvety, slightly irregular and markedly congested.

Microscopic examination of the section showed it to consist of numerous spindle shaped cells arranged in concentric layers, containing a small amount of interstitial connective tissue and a large number of thin walled blood vessels. The stroma was increased in areas but the tumor for the greatest part consisted of cells which did not stain with the Fuchsin or the Van Gieson Stain, indicating their myomatous origin. A diagnosis of leiomyoma of the uterus was made.

On April 14, 1921, the patient arrived from Seattle where she had been under the care of Dr. C. S. Leege for the past six months.

She had lost fifteen pounds in the past six months and complained of pain in the abdomen at various times in the day and night. The pain was described as gas pains and migratory, but usually began in the left hypochondrium and passed to the right and downward toward the cecum. She had difficulty in getting the bowels to move, requiring enemas to move them. The patient felt a tumor mass about a month previously.

The x ray examination (enema) showed the last third of the transverse colon to be adherent on the outside to a tumor in the general region of the lower pole of the kidney. The tumor being about the size of a doughnut, not painful. Movement of the tumor caused movement of the bowels. There seems to be a slight stricture of the bowel at this point. The stomach filled well, was very spastic and showed no signs of a tumor. A diagnosis of tumor of the transverse colon was made.

At operation on April 16, 1921, a left rectus incision fifteen cm. long was made. The omentum was found to be adherent to the old scar and the stump of the uterus. The adhesion to the anterior abdominal wall was very firm. The mass could be brought up through the incision and was found to be located on the transverse colon near the splenic flexure and was forming a part of the anterior wall, and covered with peritoneum and omentum. The vessels on the surface of the tumor were normal in size. The colon was dark red and firm in consistency. There were no adhesions to the tumor. Posteriorly to the tumor the colon was distinctly visible and uniform in size, the mass evidently not interfering with the lumen except from pressure from without. Stomach, liver, both kidneys and gallbladder were normal in size, shape and position. The pelvis was clear except normal right ovary. The colon throughout was small in calibre. No enlarged lymph glands were found.

The tumor was removed with about one and a half inches of colon on either side of the mass and a lateral anastomosis of the mesial end with the sigmoid as the mesiocolon at the splenic flexure was too short to bring it over. The wound was closed without drainage. Microscopical examination showed leiomyoma. Patient made an uneventful recovery.

Case II.—Mrs. F. H. Admitted January 4, 1922, complaining of three palpable masses in the lower portion of the abdomen in and adjoining the line of incision of an operation performed two years previously for the removal of an abdominal tumor. Examination showed three round and movable tumors about the size of small oranges in the hypogastrium. They were attached to the anterior abdominal wall. Bimanual examination showed a movable round mass in the abdominal cavity occupying the region of the left ovary about the size of a large orange. The previous operation consisted of the removal of a papillary cystadenoma of the right ovary.

Five encapsulated tumors were removed from the anterior abdominal wall and the cyst of the left ovary. Microscopical examination of all the tumors showed papillary cystadenoma. It was found that at the first operation the tumor was broken up in its removal and portions of it became scattered in the abdomen as well as in the incision.

COMMENT.

A tumor of the abdomen may acquire a new attachment to some adjacent organ, when its pedicle becomes twisted, and continue to grow in a new locality, supplied by blood from the new pedicle, or a piece of a benign tumor may migrate in the abdominal cavity and become attached to any organ and begin a new growth by transplantation.

From a diagnostic viewpoint the only possibility of making a preoperative diagnosis would be in a case where a careful history showed a preexisting tumor having changed location and with symptoms suggesting a history of strangulated pedicle, or the presence of a tumor in the upper abdomen with or without symptoms following the removal of a myoma or cystoma.

Iodine and Iodotherapy Based on a New Iodine Preparation

By HARRY J. NOVACK, M.D.,
Philadelphia

Although iodine was discovered in 1812 by Cortois, it was not until 1819 that it was first employed as a medicine by Coindet, Sr., of Geneva, and has since become one of the most important therapeutic agents.

The therapeutic results and phenomena herein recorded are based upon the use during a period of six years of two preparations of iodine of my own modification, one containing iodine alone and the other iodine and bromine. Though they are not true colloids of these elements, they are colloidal forms truly compatible with the human body and have named them colodine and colobromidine. True colloidal iodine—that produced by electrolysis in which microscopic particles consisting of clumps of iodine molecules are liberated and held in suspension in an aqueous medium—is of no greater value in the body than an alcoholic or aqueous solution of iodine; all are precipitated and converted into iodides prior to absorption into the blood. Besides, a true colloidal iodine is unstable, remaining so only a very short time after preparation, reverting into a plain solution of iodine and hydriadic acid.

Colodine is prepared from pure resublimed iodine by an electrochemical process whereby the iodine vapors during sublimation are fed through an oily medium until combination is effected. The result is neither an absorption product nor a solution but a chemical combination, in which the iodine is held strongly enough to withstand decomposition by the digestive fluids and bases, yet loosely enough readily to give up its total iodine content where most needed after absorption. It is a coal black, neutral, oily liquid, slightly heavier than water, specific gravity 1.0059 at 17° C. (62.6° F.), faint oily odor and slight metallic taste, containing ten per cent. iodine in chemical combination. It is insoluble in alcohol or water, but entirely soluble in all proportions of ether, chloroform, carbon disulphide, vegetable and mineral oils and fats.

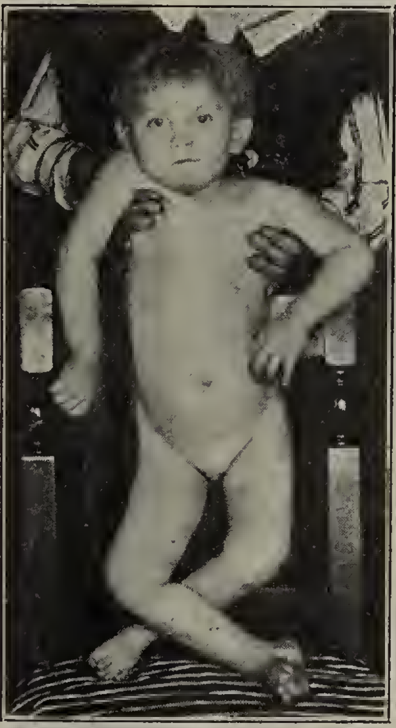

Fig. 1.—One of the patients (M) upon whom the new preparation was employed.

Colobromidine is prepared from colodine by the addition of elementary bromine vapor until combination is effected. It is physically similar to colodine except more viscid and heavier, specific gravity 1.0909 at 17° C. (62.6° F.) and contains ten per cent. iodine and twenty per cent. bromine in chemical combination. No potassium or sodium iodide or other material is used as an aid or intermediate in either preparation. Colobromidine is used where the sedative action of pure bromine is desired in addition to that of the iodine and since its administration is similar in every way to that of colodine, the term colodine will be used as synonymous for both preparations.

In vitro, colodine is but feebly antiseptic, registers the presence of free iodine but slightly, and is apparently an inert product. Ehrlich, however, showed that the efficiency of any given substance need not necessarily be the same in vitro as in vivo. On the contrary, some of our most active chemotherapeutic agents, such as arsenobenzol, only develop their full effect in the living organism, while they are practically inert in the test tube. He also furnished the important proof that a substance can only exert a therapeutic effect if it is held by, and linked up with, the cells that are to be acted on, i. e., in the case of infectious diseases, the pathological microorganisms in question.

Colodine is apparently nontoxic, as I have given in some cases a daily dose of one ounce without any untoward symptom. This is due, first, to its being bland and nonirritating to the stomach; second, its very gradual absorption and deposition in the tissues; third, its very rapid elimination.

Being a fat, colodine passes through the stomach unchanged into the intestines, where, during the course of digestion, only a very trivial part is converted into salts by the bases present in the alkaline fluids. The bulk, however, is absorbed like all fats directly into the circulation, aided by the action of the leucocytes, carried to every part of the body, where the iodine content is gradually liberated to combine with the bases, byproducts and lipoids present in the blood and tissues. A part is deposited in the tissues as fat, from which the iodine radicle is also gradually and continuously given up, resulting in deeper iodine therapy. Continued colodine administration depletes the body of most free and easily dissociated bases, resulting in purer iodine medication. It can be detected in the urine, sweat, tears, or saliva by adding a portion of starch or starch water and a little nitric acid to free the iodine from its salt compounds, when the characteristic blue color will appear.

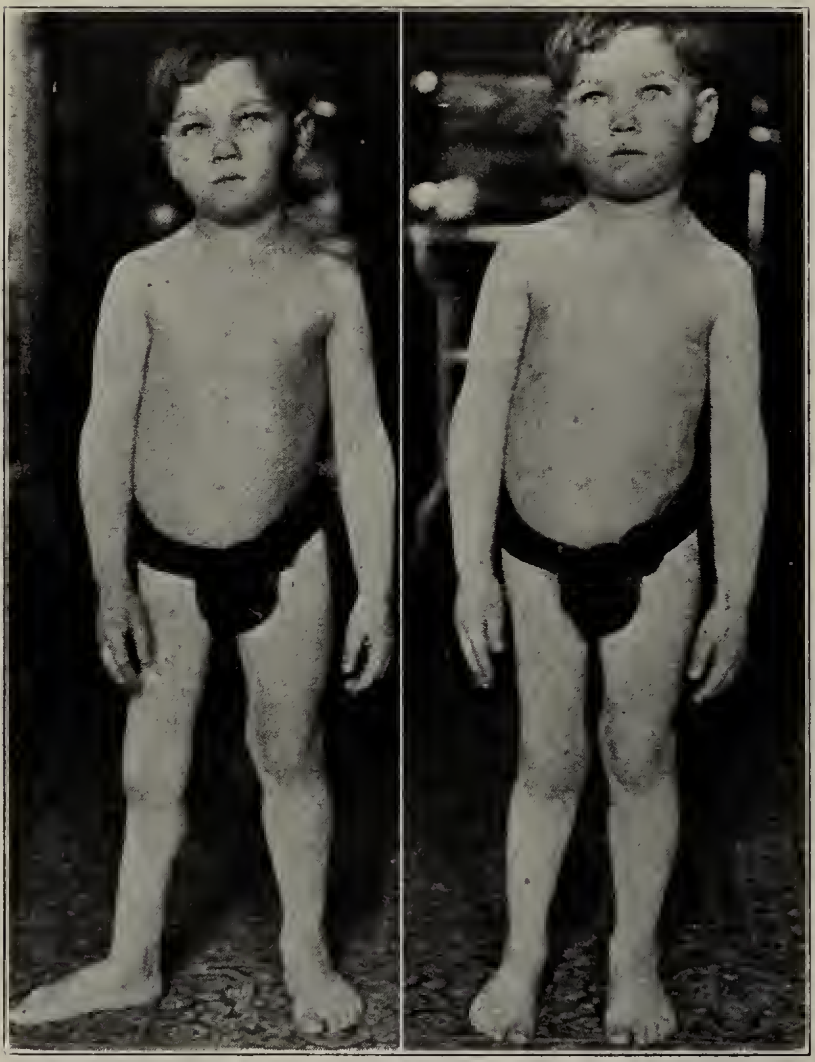

FIG. 2. FIG. 3.
FIG. 2.—One of the cases (J. R.) where the new preparation was used.
FIG. 3.—The same patient at a later date.

Not only does iodine sensitize infectious bacteria—which are colloids and lipoids suspended in a soft medium containing different salts—but also enhances the germicidal efficiency of the phagocytes themselves. This action of iodine is intensified to the greatest degree by colodine since the phagocytes play an important rôle in its absorption from the intestines where they come directly in contact with it.

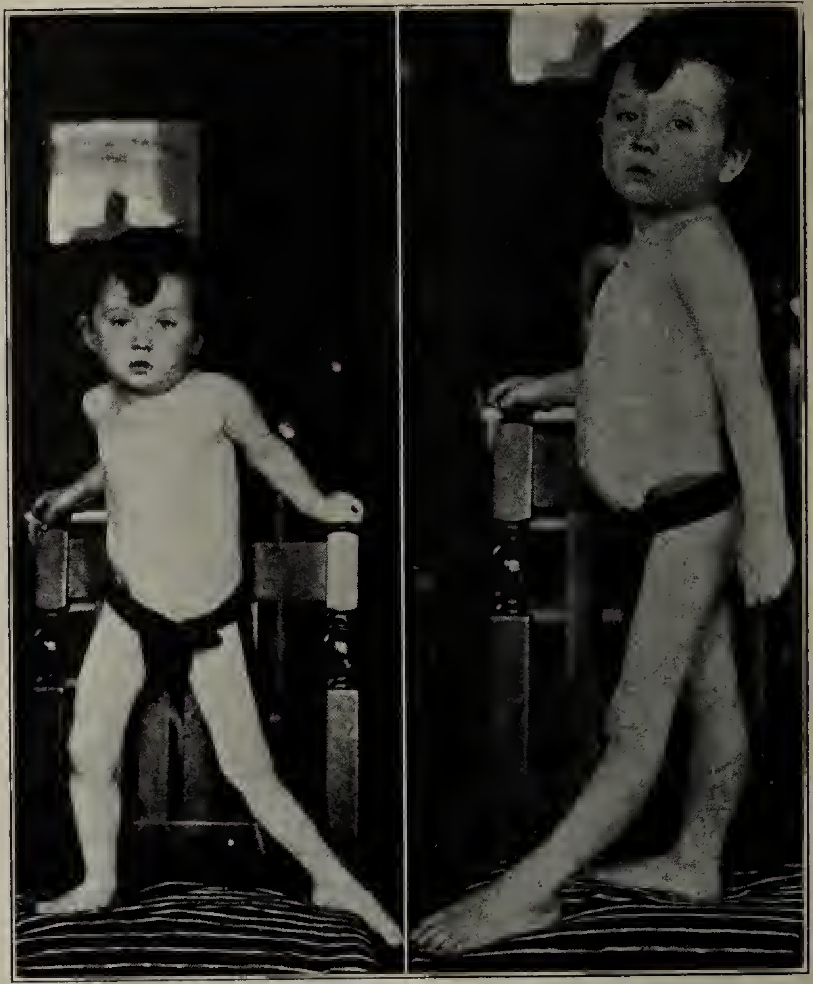

FIG. 4. FIG. 5.
FIG. 4.—Case I., J. H., showing condition before administration of treatment.
FIG. 5.—Another view of the patient in Fig. 4.

Another important action of iodine that is rarely considered is its influence upon the viscosity of the blood which it lowers. Since in most acute and chronic inflammations of bacterial or other origin there is present a coagulation process with engorgement of the surrounding capillaries, a decrease in viscosity of the blood is an important and desirable action and renders the possibility of fresh blood

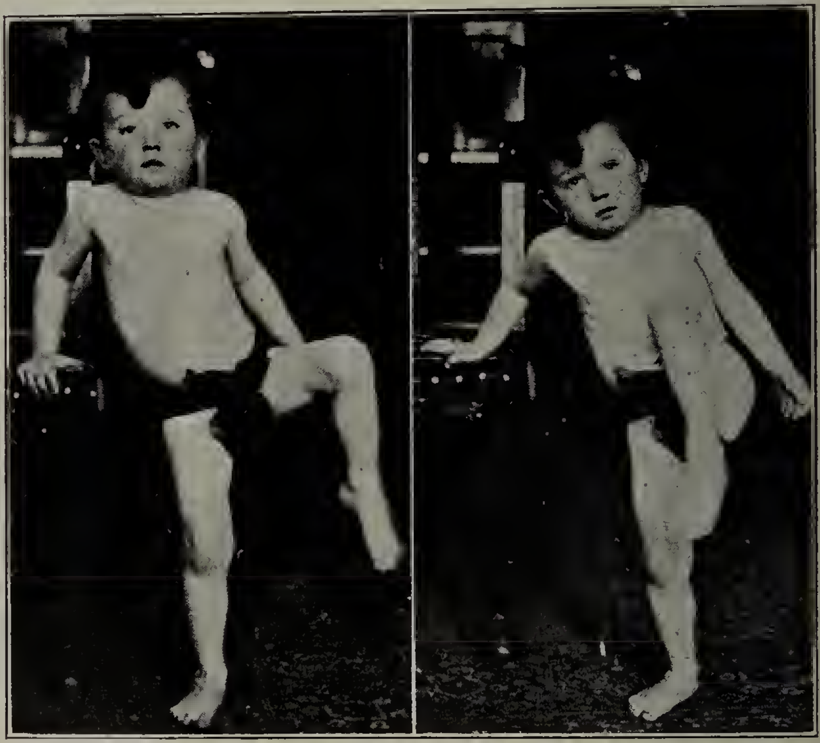

FIG. 6. FIG. 7.
FIG. 6.—Showing condition of patient (Case I.) after administration of treatment.
FIG. 7.—Movement of patient after treatment (Case I.).

reaching the sites where most needed in order to carry on successful phagocytosis and cure. Then again, in arteriosclerosis, atheroma and senility, blood of a lowered viscosity will flow through capillaries that it would otherwise block and obliterate.

In the normal individual, free from past or hidden present infection, the action of colodine in average doses of ninety minims daily, is that of mild general stimulation. Urine, saliva, respiratory and cardiac action are slightly increased. Continued medication gives a sense of wellbeing by gently stimulating metabolism in general and an increased feeling of warmth due to the increased amount of blood reaching the surface of the body. Never so-called iodism, only in some cases a metallic bitterish taste in the mouth which disappears in due time, or is gotten accustomed to and not noticed. Leucocytosis is so slight as to be barely noticeable. No appreciable rise in blood pressure which no doubt would occur as the result of the slight cardiac stimulation, were it not balanced or neutralized by the lowered viscosity of the blood and dilation of the capillaries. Appetite is stimulated and, together with the increased metabolism, a gain in weight results.

In the average individual the action of colodine differs according to the condition of the system. At first there is that same sense of well being and mild stimulation as in the absolutely normal individual, gradually followed within an indefinite time —a few days to a few months—by an exacerbation or awakening of symptoms referable to a present, recent or past infection. It is in these individuals that increased leucocytosis results, varying in degree with the nature and number of infectious bacteria liberated by the colodine. The increased leucocytosis brought forth by iodine is therefore only secondary to its primary action or that of releasing the infectious material hidden and held in abeyance in some part of the body like the tonsils, nasal mucosa, sinuses, skin, glandular system, lungs, joints or any other tissues affected.

Briefly, the cardinal points with reference to the action of colodine are: First, antimicrobic. a. It bares the infectious bacteria by stripping chemically and otherwise the natural protective material or wall which the body in its defense has thrown around them. b. It sensitizes and weakens the bacteria, as previously mentioned but to a greater degree than do the salts of iodine. c. The leucocytes already stimulated by the colodine and finding the former imperfect defense weakened or eaten away and activation of the germ nest beginning, are forced to fight, producing the typical colodine reaction at site of infection, typical of any acute infection but with the balance usually in favor of the phagocytes and the body. Second, the lowered viscosity of the blood and dilatation of the superficial as well as deep capillaries, increasing metabolism, and aiding the first or antimicrobic action. Third, general eliminative action of excess bases, insoluble calcium, metabolic byproducts as well as mercury, arsenic and lead. Fourth, general endocrine glandular stimulant and activator, equivalent, if not superior to that produced by glandular therapy.

INDICATIONS.

Iodine medication has usually been associated with the treatment of subacute and chronic affections and only recently has it come forth as being of value in acute diseases.

The indications mentioned below are based on the results of years of study in a large number of varied cases and involves the use of over 250,000 adult doses of thirty minims of colodine representing a total of over one hundred pounds of crystalline iodine.

Generally, colodine has been used with unusually good and often miraculous results in the following conditions: Acute and chronic tonsillar infections; acute, subacute, and chronic rheumatic affections of the joints, muscles and nerves; endocarditis and valvular diseases of the heart; acute, subacute and chronic glandular infections and swellings; simple and exophthalmic goitre resulting from focal infection; catarrhal pneumonia; bronchial asthma; hay fever, acute and chronic bronchitis and pleurisy; acute and chronic laryngitis and spasmodic croup; just before and following crises in lobar pneumonia; acute and chronic gonorrheal infection of any part of the urogenital tract; gonorrheal rheumatism; primary, secondary and tertiary syphilis; scarlet fever; atheroma and arteriosclerosis; high blood pressure, especially that resulting from focal infection or sodium chloride irritation or syphilis; paralysis following an apopletic stroke as well as that resulting from acute anterior poliomyelitis; senility; as an emmenagogue and endocrine glandular stimulant; abscesses, boils, carbuncles, erysipelas, cellulitis and various eczematous skin affections.

In acute tonsillitis, especially where the streptococcic strains of bacteria are predominant, colodine is specific. After ten or twelve hours of intensive medication, thirty or forty-five minims every two hours, despite the fact that the reaction causes increased swelling of tonsils, peritonsillar tissues, and in some cases tenderness of the muscles and glands of the neck, pain, discomfort and temperature are much lessened. Given early its action is abortive in one or two doses. In most cases within twenty-four hours a typical crisis occurs with perspiration and rapid fall in temperature. Continuation of average medication, thirty minims three or four times daily, insures rapid recovery and safeguards the heart and joints from involvement.

In acute articular rheumatism, particularly that resulting from focal infection, colodine is specific. Reaction and cure are affected in a comparatively short time despite the fact that the original site or focus is not removed. The joints last involved are the first to react and swellings may often increase to such a point where one is tempted to incise in order to drain, but this should never be done as gradual recession automatically takes place. Some passive and active movements of the affected joints should be carried out daily to prevent fixation. The heart, if not already involved, is rarely infected after the body is saturated with colodine. When the endocardium is involved, the good effects of the medication are such that when acute symptoms recede it is left with a minimum or no permanent damage. Colodine in this condition is much superior to the salicylates which have the distinct disadvantage of producing marked proteinuria and casts when given in large doses, and have often wondered if they have not the special ability of weakening the endocardium thereby rendering it more susceptible to involvement. After the joints are normal, foci of infection should be removed.

In chronic arthritis colodine causes a more prolonged but attenuated reaction and gradual clearing of the joints. It can be used over a long period of time. Foci of infection should be removed when possible and in intractable cases treatment may be aided with physiotherapy, vaccines or other means desired.

In acute or subacute gonorrheal rheumatism when used fairly early colodine is specific, producing a decided reaction and recession to normal similar to that in the streptoccal joint infections. When uretheral infection is still present, the flow of pus is usually increased. Fixation of joint or joints is not advisable, instead, passive and moderate active motion to prevent ankylosis. Cases apparently crippled return to normal within three to six weeks under colodine medication.

In acute gonorrheal urethritis it has proven to be the best internal remedy for the system. There is an immediate fixation or limitation of parts already infected as evidenced by the characteristic reaction produced, i. e., increased swelling of penis, testicles or glands in the groin, with increased discharge, gradually followed by recession and a thin discharge requiring only a simple astringent to complete the result. Medication should be continued for a time after all symptoms are cleared. Some patients starting treatment after a period of selfmedication and neglect, may complain of pain in one or more joints when colodine is given, showing that the infection was on the threshold of producing an arthritis. This subsides rapidly even before the cure of the uretheral infection. No special diet was given in any case nor was liquor forbidden in individuals accustomed to it. Cures have been proved by the microscopic examination of urine, prostatic and seminal secretions and complement fixation test, and some patients are still kept under occasional observation. The average time required is from one to three months or a little longer when there is a history of previous attacks, but there is that satisfaction of feeling that the genital organs are left in an absolutely normal condition and not with a hidden germ nest in the glands or other tissues for future activation.

Chronic gonorrheal urethritis with a history of many acute exacerbations over a prolonged period responds to the clearing action of colodine more so than to any other known treatment, not excepting vaccines. Within a short time after starting medication a discharge appears, or if already present is increased, with but slight reaction and tender points over the urethra or other parts involved. The discharge may cease or lessen and then start or increase again. This may occur several times during a period of three or four months, giving one the impression that multiple hidden nests of pus were reached and emptied. Finally all discharge ceases. An astringent should be used during the last month or two but this does not influence the attacks of discharge produced by colodine. The average time of treatment in the most chronic case was five months, with complete cessation of discharge during the last month.

In boils and carbuncles, even those occurring on the upper and lower lips, the antimicrobic power of colodine is noticeable, causing rapid expulsion of the core or cores with hastened resolution and healing. A small opening, if not already there, should be made but not large enough to disturb the natural protective wall in any direction. Continued medication prevents the formation of additional infective sites by raising the resistance of the individual. When desired, vaccines, heat, and local applications may be used as aids. In abscesses the action is similar, but when resolution results they must always be opened in much less than the usual time with rapid dissolution of the hardened base and a minimum of scar tissue.

In scarlet fever colodine is superior to any known medication, protecting the heart, preventing complications, and shortening the duration of the disease. Desquamation usually begins on the third or fourth day instead of the eighth or ninth and ends much sooner. In severe cases with hyperpyrexia, ulceration of tonsils and uvula and swelling of the neck, large doses should be used; in a child five or seven years of age forty-five minims every two hours for ten doses, then thirty minims every three hours, or three or four times daily till complete recovery.

In broncho pneumonia its action is very decided, checking the progress and clearing the lungs in days instead of weeks as is usually the case. Its action is not so brilliant in the lobar types of pneumonia but is of great service in hastening resolution, preventing complications and shortening convalescence.

In amenorrhoea colodine is a very potent drug. By thinning the blood, dilating the capillaries and stimulating the thyroid, pituitary, as well as the other endocrine glands, it will often cause to continue for months the menstrual cycle even in those cases on the menopause borderline. It should therefore not be used in the early days of pregnancy as it will in the majority of cases cause separation of the feebly attached impregnated ovum.

In the paralysis resulting from acute anterior poliomyelitis the results with colodine are worthy of note. The first action is that of increased warmth in the paralyzed limbs followed in a comparatively short time by the regain of muscle function and increase in muscular power generally. In a child of five or six years of age thirty minims three times daily (the adult dose) are given. Within two or three months a reaction rendering patient inactive, indisposed and lazylike, calls for a cessation of medication for a week. It can now be resumed in full doses until similar reaction occurs or else half the dose may be given and continued indefinitely. Its mode of action in these cases is as yet not clear unless it increases the nerve force carrying power of the uninjured nerve fibres, or else saturation of the body with the drug may render the muscles more sensitive to feeble impulses. That iodine has the power to enter the spinal cord is well known and possibly in that way clearing away the débris relieves the uninjured nerve elements from pressure. It is not meant that muscles completely atrophied will be rejuvenated, but, as will be seen in cases reported herein, almost completely atrophied muscles have regained their action in as comparatively as short a time as in the more recent cases. Shortened tendons and contractures must be surgically corrected, but minor deformities due to overactivity of one set of muscles and paralysis of the opposite set should not be interfered with surgically, but mechanically and manually exercised and corrected until the paralyzed side becomes rejuvenated by the medication, thus aiding in the correction of the deformity. In the acute stage of this disease I have not had experience.

ANTERIOR POLIOMYELITES.

Case I.—John H., three years eight months old, referred on January 6, 1922. His mother, twenty-three years old, and father, twenty-four years old, were both living and well. Birth was normal and he had been breast fed. His present illness began on October 10, 1921; after slight fever he suddenly found that he couldn't walk. Both legs were paralyzed and after being confined to bed a month right leg became almost all well. Physical examination showed tonsils, negative; heart, negative; pulse 112; right leg normal; left leg all muscles paralyzed except a little life in the iliacus and psoas magus, so that he could flex thigh on abdomen, raising foot one inch from ground and rotate slightly outward. All other muscles dealing with movement of thigh, leg, foot or toes in any direction were completely inactive. The entire left leg from groin to toes was several degrees colder than right leg and somewhat discolored with bluish mottled spots. The left leg was atrophied and about one third less thick than right. He threw his left leg and foot outward when walking or standing and the knee was thrown backward giving the leg the shape of a bow with the convexity in the back.

Treatment: colodine, in thirty drops floated on a teaspoonful of water, was given three times daily. Thermopenetration with pads six by eight inches over spine and abdomen, 1000 ma. for ten minutes interruptedly. Sinusoidal and vibratory ten minutes each. At first treatments were given triweekly then reduced to once weekly. The treatment was begun on January 6, 1922. On January 10, 1922, the leg became warmer from groin to knee; January 13, 1922, raised thigh to fullest limit flexing it on abdomen, warmth extending to middle third of leg; January 16, 1922, could flex all toes of left foot except large toe; January 20, 1922, could flex leg on thigh feebly but not extend; January 23, 1922, could extend leg feebly when in lying position and on smooth surface; January 30, 1922, flexion and extension of leg much increased and strengthened; March 13, 1922, slight motion in ankle appearing; March 22, 1922, all muscles involved were hypersensitive and tender, particularly the soleus and peronei. The skin was also hypersensitive. Child felt lazylike and the drug and treatment were discontinued for a week until reaction abated. Thus far, station was perfect. Walking showed slight limp due to lack of power in ankle. The child did not throw his leg as previously, but stepped forward naturally and until reaction came he would romp around all day without getting tired or fall. I am confident that with very little additional treatment full muscle power will be regained in the ankle which is all that is now lacking. On April 20, 1922, he could flex, extend, abduct and adduct ankle with a light weight placed on plantar side of foot.

Case II.—Frieda M., two years eight months old, referred on January 15, 1922. Family history was negative. Past history showed that she had had measles. Present illness began with infantile paralysis on July 12, 1920, when she was in the hospital for three weeks. The right leg became paralyzed first, then the right arm and left leg. Physical examination showed that she wore braces, but could not walk, stand, or even sit erect of her own accord. Right leg and hand felt cold. Left leg had all degrees of motion, i. e., adduction, abduction, rotation, flexion, extension, but was very sluggish and weakened. There was diminished sensibility in all parts affected. Right arm hung lifeless at side of chest, atrophied to one half the thickness of the left hand; humerus was out of the glenoid fossa and head could be felt on top as well as on the sides; the hand was only slightly affected. The right leg was completely paralyzed and without the least motion obtainable in any direction. Muscles of back were partly paralyzed so that sitting was difficult without some support.

Treatment.—Braces were discarded. Colodine in thirty drop doses was given three times daily. Thermopenetration over spine, also monopolar vacuum electrode over surface, sinusoidal and vibratory as in former case, first twice, then once weekly. On January 17, 1922, the right leg became warmer and the patient could lift thigh in flexion one-quarter inch. On January 21, 1922, while in dorsal position, she moved right thigh outward six inches, inwards two inches, and flexed thigh upwards so that knee was raised eight inches. On January 28, 1922, she could extend right leg slightly. On February 8, 1922, she could extend right leg with force and very slightly flex it. February 14, 1922, flexion and extension of leg was definite and increased. On March 1, 1922, she could sit erect without aid, turn over on her back or abdomen with her own effort and flex both legs to the full limit while on her back. Right arm was much developed in thickness, and she could adduct, abduct, rotate arm and flex and extend forearm feebly. Right ankle and toes were still lifeless. Right arm had been almost completely drawn up into socket. On March 1, 1922, she was languid, lazylike and indisposed, therefore medication and treatment were discontinued until reaction passed. March 8, 1922, she had power to rotate right thigh and showed increased strength in all muscles. March 29, 1922, she was able to raise herself from dorsal position without aid.

Case III.—Charles C., aged four years six months, was referred on January 9, 1922. He became ill with infantile paralysis in August, 1918, when fourteen months old, and was ill for two weeks with fever and not well for three weeks afterwards. It was noticed that both legs were paralyzed. Physical examination showed that he wore ankle brace on left leg and a brace past the knee on the right leg. There was a scar of an operation over the right hip which corrected outward deformity and apparent elongation of leg. Right leg was atrophied to about half the size of left leg in thickness. Left foot turned outward and was not corrected by brace which he wore. Could not stand without support.

Treatment.—Braces were removed and manual turning of left ankle inward ordered, forcibly flexing and extending it so as to stretch the tendoachilles which was partly contracted. Colodine was given in doses of thirty drops three times daily. One electrical treatment weekly similar to former case. On January 23, 1922, he could flex and extend right leg feebly when on the abdomen. January 31, 1922, could flex and extend left ankle and turn it inward slightly. February 21, 1922, right ankle showed slight extension movement. March 14, 1922, left ankle was much straightened by the activity of the muscles drawing foot inwards. April 4, 1922, had definite motion in right ankle of flexion and extension, also increased power of flexing and extending right leg and could stand erect unaided and walk a little when held by the hand. Treatment was continued.

ADMINISTRATION.

Being a heavy oil, colodine is best administered in 00 hard gelatine capsules filled to a concave meniscus and sealed dry. Such capsule will hold fifteen minims or twenty drops of colodine, two of which are an average dose. In chronic conditions thirty minims three times daily is an average dose. In acute conditions or where rapid saturation is required, thirty minims every two hours may be given for several days when necessary. In children of four to eight years, average dose is twenty drops or fifteen minims three times daily in chronic conditions and may, however, be doubled when required as they seem to tolerate more iodine than adults. It is best given floated on a little water in a teaspoon or mixed with mineral or olive oil. In acute conditions twenty to forty drops every two hours is easily tolerated. For infants, ten drops three times daily in subacute or chronic conditions and ten drops every three hours in acute diseases.

In all painful conditions the addition of the bromine has proven of great value as a sedative. In urethritis colobromidine lessens the tenesmus and chordee. In arthritis it lessens the pain somewhat and gives better sleep. The dose and administration of colobromidine is identical with that of colodine.

It will readily be appreciated that a drug of such low toxicity and high and unusual therapeutic powers should lend itself to a wide range of application in the treatment of disease. In reality, the action of colodine is dependent upon its ability to stimulate the natural forces of the body in its fight against disease, to a point beyond which they usually cease to operate and are content to keep in abeyance within the body the infective organisma.

A Biochemical Explanation of the Iodine Molecule

By P. R. VESSIE, M.D.,

Gowanda, N. Y.

Fats are digested by lipase, a pancreatic ferment. This neutral fat is converted principally into fatty acids and glycerin. The fatty acids are rendered by the alkalies into soap, a water soluble fat. The soap is readily absorbed by the intestinal epithelial cells (1) and transported into the circulation. It is then resplit into fatty acids and these molecules anchor themselves to components of the tissue-cell, such as lecithin (2). The fatty acid molecule (3) serves the function of liberating energy. Since the carbon atoms constitute, with hydrogen and oxygen, the organic acid molecule, their explosion is produced by oxygen. But the amount of oxygen in the fat molecule is insufficient to oxidize its carbon and hydrogen atoms, the transportation of additional oxygen being necessary to effect an explosion of this molecule. A complex iodine, which circulates freely in the circulation, is apparently responsible for the direct introduction of oxygen.

A large list of fresh foods contains iodine (4). During proteid digestion it is presumed that traces of iodine, like other food chemicals, combine with amino acids to form iodoamino acid and in this common process it ultimately associates itself with the nucleoproteins of the body (5). Specialized cells in the thyroid gland apply a remarkable power of selection and absorb this amino acid to prepare a synthetic iodine derivative, "thyroxin" (6). Studies in metabolic rate (7) demonstrate the tremendous activity of a minute quantity of thyroxin in the process of speeding up the elimination of cell waste by oxidation; and, as this chemical element can remain in the living organism and decarbonize cells for days (8), without deterioration, it must be regarded as a true catalyst (9). It is quite probable that thyroxin brings the essential oxygen in immediate contact with the carbon of the cell. Carbon dioxide, resulting from oxidation of the organic acid molecule, acts as a stimulant to the respiratory centre. The function of iodine may be summarized by the following steps:

1. Absorption of iodine-bearing food.
2. Formation of iodoamino acid.
3. Reconstructed iodine, thyroxin.
4. Thyroxin as an oxygen carrier.
5. Oxidation of the fatty acid molecule.
6. Formation of intermediate products (10).
7. Carbon dioxide, the final end product.
8. Stimulation of the respiratory centre by carbon dioxide.

When there is evidence of simple thyroidism or defective nutrition resulting from suboxidation, thyroid substance, thyroxin, or small quantities of iodine have their activating effects on the thyroid gland and the tissue cells. But where there is some gross pathological lesion, such as a necrotic lesion or glandular enlargement, a more definite explanation of the therapeutic action of iodine is necessary. The leucocytes carry the molecules of fat to the local site of inflammation to retard the increased combustion of tissues. In this attempt the lesion becomes overstocked with lipoidal (11) substance and the consequence of this excess is an impairment of local oxidation. By systematically saturating fractions of the fatty acids with iodine (12), resolution of lipoidal substance occurs. The chemical alteration of these fatty acid radicals in the lesion alienates this type of fat, exerts a reducing effect, and liquefaction is the result. Thyroxin, the oxygen carrier, then has access to the individual cells and eliminates their carbon waste, accelerating the oxidation of abnormal fibrous tissue and the replacement of normal cellular arrangement.

Immobility of the Diaphragm, With Report of Cases of Bilateral Immobility

By JOHN H. PRYOR, M. D.,
Buffalo, N. Y.,
Chief Consultant, J. N. Adam Memorial Hospital, Perrysburg, N. Y.

A previous communication, based upon a clinical research in eighty-four patients who had suffered from pleurisy with effusion or empyema, was published in 1916. The mobility of the diaphragm was determined by the use of the fluoroscope, and the opinion that the damaging effects of pleurisy and empyema were far more frequent and serious than had been assumed, was justified. Since that time, opportunity has been afforded to examine others and collect the whole number in a series of 145 cases. The interval between the time of aspiration or evacuation and examination of all cases was about a year and a half. No cases were included except those in which fluid was withdrawn and they may be classified in five groups:

1. Empyema in the child.
2. Empyema in the adult.
3. Pleurisy with effusion.
4. Pleurisy with effusion, and clinical pulmonary tuberculosis.
5. Pneumothorax and effusion.

In the complete series, the conclusion may be drawn that one individual of six escapes with the action of the diaphragm unimpaired. About the same proportion had more or less restricted, comparative motion and in two-thirds of the aggregate all motion on one side was lost. An extended, statistical analysis and tabulation, showing the effect upon the dome, and cardiac and costal sulci will be found in the previous article, and any further discussion of the statistical data will be limited at this time to general conclusions.

EMPYEMA IN THE CHILD.

In empyema affecting the child, fixation of the diaphragm is much more infrequent than in the adult. The tendency to more rapid recovery is apparent and the resultant damage less, with the exception of involvement of the pericardial pleura, and the displacement of the heart. I have reported a number of cases where the position of the heart was changed to an extreme degree and followed by apparent recovery from empyema with a hopelessly incompetent heart. Many times prolonged duration of empyema in the child with irreparable injury to the diaphragm and the heart, have come under observation and are explained to a large extent by incomplete evacuation, undetected pockets, the tendency to allow a premature closure of the opening for drainage and delayed or insufficient attention to the expansion of the collapsed lung. Experience has led to the conviction that the claims made for the benefit derived from the employment of Dakin's solution have been much exaggerated, so far as empyema in the child is concerned. Immobility of the one leaflet followed empyema in the child in about fifty per cent. of those observed. The fact must be emphasized that resultant loss of function of the diaphragm may not be demonstrable for a varying period after recovery. The leaflet may be mobile, or restricted in action for months and upon later examination show complete loss of motion. It should also be remembered that the unnecessary removal of sections of ribs in the child leads to contraction of the chest wall and mechanical restriction of the full length of the leaflet.

EMPYEMA IN THE ADULT.

In the adult empyema is a far more serious disease, and the probability of the crippling of a leaflet of the diaphragm on the affected side is decidedly increased. Of fifty patients observed from three months to eight years after recovery only eight revealed no evidence of loss of motion, flattening of the dome or obliteration of the cardiac or costal sulcus. Why the small percentage escaped is inexplicable, as several of them were severe, intractable cases. One patient who escaped without injury to the diaphragm had a recurrent empyema eight years after the first attack, on the same side, and the case was reported because of its rarity. Accumulated experience during the last six years has strengthened the opinion that consequent adhesion to the pericardium and malposition, with occasional surprising twisting of the heart, form a very important factor in the results and explains symptoms and complaints often overlooked or ascribed to other causes. We find that a cardiac murmur, distinctly audible while fluid is present, disappears quickly after evacuation and also that heart sounds which were normal before an attack later displayed many manifestations of disturbed action, if an exercise test is employed. Pericarditis occurs much more frequently as a complication of empyema and pleurisy than is commonly supposed. There can be little doubt that a purulent pericarditis is one of the associated, grave conditions in fatal cases, and it is practically impossible to detect its presence until disclosed at autopsy.

PLEURISY WITH EFFUSION.

When the results of pleurisy with effusion are compared with those after empyema they are found to be more encouraging. Loss of function of the affected leaflet does not occur in such large proportion. In about half of those observed some motion of the diaphragm is maintained, but only about twenty per cent. show full motion with preserved contour of the dome. Thus about eighty per cent. of the group revealed loss of motion or varying degrees of restriction, loss of the curve of the dome or obliteration of the cardiac and costal sulci. It is in these cases that adhesions and contraction play a larger rôle, and in the past led to the misleading assumption that fixation by adhesions was entirely responsible for immobility. Undoubtedly exudate and residue in the sulci are responsible for the fibrinous deposits which later become organized and interfere with function, but these factors do not account for the changes which take place in the diaphragm. We have frequently demonstrated the fact observed in 1915, that it is impossible to remove all the fluid in the pleural cavity by aspiration. Some of the exudate always remains in the costal sulcus and more accumulates before recovery. The amount of fluid present and the elected time for aspirations seem to make slight difference, if any, so far as the effect upon the diaphragm is concerned. In fact, a dry pleurisy may as effectively produce immobility. The amount of fluid may be small and aspiration considered unnecessary, as in many patients when pulmonary tuberculosis is associated. When aspiration is performed the results are approximately the same as in pleurisy with effusion and no clinical evidence of pulmonary tuberculosis.

PLEURISY WITH EFFUSION AND PULMONARY TUBERCULOSIS.

In this group mention is made only in a statistical compilation of those cases which revealed unilateral immobility. Much assistance was rendered by the physicians at the Adam Hospital at Perrysburg. The results differ very slightly from those of pleurisy with effusion. About half the number were followed by complete immobility of one leaflet and only about twenty-five per cent. had full, normal motion with no apparent involvement of the dome and the sulci. It is in this class of cases that we may look for bilateral immobility, as will be shown later.

PNEUMOTHORAX.

Brief reference is made to pneumothorax as a cause of marked immobility. If the pneumothorax is accompanied by a pleuritic effusion, the ultimate effects are similar and require no special mention. The frequency of pleurisy, provoked by artificial pneumothorax, is thoroughly recognized and reported by conscientious observers, but the remote danger of crippling the diaphragm seems to be disregarded. There can be no definite assurance that a pleurisy may not develop at any time in the other side, and bilateral immobility, with all its disastrous results, may supervene.

EFFECT UPON THE LUNG AND HEART.

Nor can we assume that a pleurisy followed by an impaired or disabled leaflet of the diaphragm will be limited to the side attacked. More than half of those examined during deep inspiration and expiration, exhibited less than normal motion, with changed configuration of the dome on the opposite side. When half of the diaphragm was fixed and the pericardium displaced and adherent, the other half was found, in a number of cases, much restricted and the dome absent. The claim, sometimes made that compensatory activity of the leaflet on the unaffected side would assume a wider scope in its rise and fall, was not realized. In only one instance was an increase of movement displayed by a remarkable excursion, and that was associated with atelectasis. Sufficient proof, supplied by clinical observation, justifies the contention which should be more widely accepted, that pleurisy with effusion and empyema must be considered as a diseased condition in which changes in the diaphragm and pericardium are always involved to a greater or lesser extent. But the question will be asked, Do the effects give rise to any impairment of health, and definite complaints? The answer must be, Remarkably little disturbance in the majority of cases. There are notable exceptions, however, and forms of invalidism may follow for an indefinite time, such as neuralgia, confined to the previously affected side, inability to perform an equal amount of work, palpitation, rapid heart action, and some disturbance in breathing when previous exercise is undertaken. In the course of time these symptoms are likely to disappear, unless adhesions to the pericardium with malposition and interference with the proper action of the heart become permanent. Of course the grave danger exists in the realization that in a very small proportion disease of the opposite leaflet of the diaphragm may develop and bilateral incompetence ensue.

BILATERAL IMMOBILITY.

From a clinical viewpoint the chief purpose at this time is to invite attention to the rare and serious condition of bilateral immobility. A persistent endeavor to detect those thus afflicted has been rewarded. In 1916 I reported one case, and to the best of my knowledge, after a careful scrutiny of the literature, it is the only one recorded. That other observers may have recognized its existence since the introduction of the fluoroscope, is probable, but if published, it has escaped notice. During the last six years, five more have been discovered. One may be briefly described and removed from the group, as it was not due to disease of the pleura and diaphragm alone, but was associated with other complications which contributed in an unknown degree to the complete fixation of the diaphragm. A physician, who had reached an advanced age and gave a history of having had pneumonia during middle life, met with a severe accident. Four or five ribs were fractured, followed by spitting of blood and a prolonged attack of pneumonia of a low grade. Later, much difficulty in breathing was experienced, and he came to me for relief from this distress. Dyspnea followed the slightest exertion and gradually became so severe that he could take only a few steps without a violent attack. The examination revealed complete bilateral immobility—a bovine heart—aortic insufficiency and a large aneurysm. Death followed soon after. The other five patients are included in a series, for clinical study. Each of them had fibroid pthisis of a chronic type in a stage of arrest. Each recollected an attack of pleurisy with effusion on one side, and one had undergone aspiration. In three cases the disease had pursued its usual course for a period of about one year, and then shortness of breath steadily increasing in severity was noticed. They were all sent to me for relief from this dominant complaint. Loss of appetite and weight were slowly progressive. All were anemic, and complained of weakness and inability to perform any work or take the slightest exercise without great discomfort. Any increase from a slow walk for a short distance was followed by distressing dyspnea. The afternoon temperature was subnormal. There was no cough and no expectoration. The blood pressure and pulse pressure were low. Upon examination, the heart sounds were weak and difficult to detect. The impact of the apex was absent and the cardiac area decidedly diminished in extent. The breathing was distinctly costal, and after any effort accessory muscles were summoned to assist in the arduous struggle for breath. After a short period of complete rest, the difficulty in breathing would subside. Palpitation and an increase in the rapidity of the heart action was observed in all. In only one instance could the vital capacity of the lungs be procured, as a proper instrument had not been acquired at that time. The test by the Sanborn apparatus revealed only twenty-three per cent. of the normal standard. It was difficult to obtain an accurate registration, as deep inspiration and expiration were a hard task. Fluoroscopic examination revealed complete bilateral immobility of the diaphragm. Both leaflets were in the lowest position—flat—and the picture was that of an inverted V, with the pericardial attachment forming the apex. The cardiac and costal sulci had lost their normal appearance, and the lungs, descended to their lowest level, displayed aeration to their deepest extent. The depression of the diaphragm was similar to that which appears with a fatal pneumothorax. But the greatest surprise was occasioned by the position of the heart and its contour. Its appearance was like that of a tube with its normal shape entirely lost. The whole structure filled a space about the size of the aorta and resembled the usual shadow of the mediastinum in the region of the aorta, until the location of the pericardial attachment was reached and there it spread somewhat like a fan, at that juncture. No pulsation was visible. The pericardium appeared to have been pulled down and stretched, until the heart, deprived of its normal space by pressure and elongation, had been forced to assume a shape never previously perceived, and to the best of my knowledge undescribed. The appearance is distinctly not that of the drop heart, atrophic heart of advanced tuberculosis, the drop heart, or the asthenic heart, which have long been recognzed by German authors. It was impossible to obtain a röntgenogram of the chest, except in one patient. The mediastinal shadow portrayed in the plate is distinctly wider than that observed in the remainder that were fluoroscoped. The three patients mentioned did not live in Buffalo, and there was no opportunity for a second examination. It was learned later that they all steadily declined. The distressing symptoms increased until death occurred. One died in three months, one in seven months, and one lingered for two years after observation. The immediate cause of death remains unknown.

ARTIFICIAL PNEUMOTHORAX AND BILATERAL IMMOBILITY.

In two patients in the series of five bilateral immobility developed after treatment by artificial pneumothorax. Both were sent to me by physicians in neighboring cities, with the request that the pleural cavity be refilled with air on a definite date. In one, artificial pneumothorax had been employed as a remedial measure, and in the other it had been produced and maintained to prevent hemorrhage. This patient gave a history of repeated attacks of hemoptysis, and the artificial pneumothorax had apparently checked them. No hemorrhage had occurred for three months. Both had been treated by repeated refills, at short intervals. One had a definite history of pleurisy with effusion, on the unmolested side. The other stated that she had had an attack of pleurisy in the past, but in neither case had fluid been aspirated. Both had suffered from chronic tuberculosis, but the disease was in a stage of arrest, and no evidence of activity could be found. In both patients the afternoon temperature was subnormal. They were well nourished, and had not noticed shortness of breath until recently, when inability to exercise and to perform the usual daily duties had become impossible. Of course the invitation to repeat an artificial pneumothorax was declined. Upon examination it was found that the injected air had not been absorbed. The apex beat was displaced, and there was evidence of slight tuberculous involvement, in a quiescent stage, in the opposite lung. Fluoroscopic exposure revealed the lung compressed against the mediastinum, both leaflets of the diaphragm immobile, in low position, and a tubular heart which had not entirely lost its contour. One patient was never seen again, but later information was supplied that she died about eight months later. The other patient was prevailed upon to allow the removal of redundant air from the pleura. The procedure was slow, with periods of rest. After about four hundred c. c. were withdrawn, she was suddenly seized with violent coughing and expectorated large quantities of fluid for about ten minutes. The attempt to avoid an attack of bronchorrhea failed. Later much relief was experienced, and the following day the respirations, which were 35 before interference, had dropped to 22. Later decided expansion of the lung took place, but dyspnea on exertion continued. After a period of one month, another fluoroscopic examination was made, and stereoscopic x ray plates obtained. Complete bilateral immobility persisted. There was no recurrency of hemorrhage. She gradually declined, lost weight, and rapidly became an invalid, unable to walk any distance about her home, or do any work requiring the slightest exertion. The tuberculosis of the lungs remained quiescent. A physician advised her to try a change of climate, and she left the city. No information as to the outcome has been received. Such disastrous results, after the improper employment of a procedure, always fraught with some elements of danger, should cause the enthusiasts to reflect and stimulate caution. One half of the diaphragm had undoubtedly been disabled, long before the other was seriously involved. The significant facts in the history to be emphasized are, that pronounced dyspnea ensued after the last refill, and the expected absorption of air did not occur in accordance with prearranged dates. My experience with artificially induced pneumothorax is comparatively slight. Patients are sent away, and intrusted to the care of conservative confrères if possible. Even when caution is urged, queer things occur in strange places, and perhaps if a thorough search were made, unreported cases similar to those reported might be recognized. In a large proportion of individuals pleurisy with effusion develops, a dry pleurisy with progressively increasing adhesions, or an empyema, sometimes alluded to as benign, after the introduction of air or gases into the pleural cavity. One should know to a certainty whether one leaflet of the diaphragm is incompetent before daring to undergo the risk of irreparably damaging the remaining portion, so necessary for the maintenance of life.

PHRENOCARDIAC INCOMPETENCE A DISTINCT CLINICAL ENTITY.

Any discussion of consequent disability, following complete destruction of the function of the diaphragm, caused by inflammatory action, must include at least two factor, viz., phrenic and cardiac incompetence. Complete fixation of the diaphragm and the physiological and pathological sequence, associated with abolition of function, will not alone account for the symptomatology. The distressing invalidism, succinctly portrayed, is unquestionably due, in a large degree, to respiratory and circulatory failure combined. The author ventures the claim, that a hitherto undescribed clinical entity, characterized by a definite and distinctive symptom complex, should be recognized and accepted, if further investigation by others substantiates the conclusion. Respiratory incapacity is one result of total diaphragmatic inefficiency, but the diaphragm has at least seven functions, more or less interdependent, and these rarely, if ever considered, help to explain the various manifestations of disordered metabolism which contribute the manifold evidence of functional debility. There is justification for the assertion, offered after reflection, that no other morbid condition is revealed through the presence of an identical or quite similar group of clinical data. Gradual immobility of the diaphragm with consequent lack of respiratory ability, associated with cardiac enfeeblement, which is apparently largely due to mechanical causes, are the agencies in the production of a condition which may be described as phrenocardiac incompetence. A suggested, tentative name assists in riveting attention upon the dual relation delineated in the clinical picture. Any resemblance to the array of symptoms cannot be recalled. They have not been seen in the course of long experience in any disease of the lungs, nor can they be ascribed to tuberculosis in any form, if unattended by involvement of the diaphragm or a tragic attack of pneumothorax. None of the patients mentioned had advanced tuberculosis or symptoms of air hunger, when the complaint of breathlessness arose. Furthermore, a careful search has failed to disclose any reference to the appearance of the heart as described. The pulling down and stretching of the pericardium is extreme and the change in the form of the heart, not previously perceived, with the mechanical interference and resultant interstitial changes in the pericardial sac and myocardium, seem to constitute a new type of cardiac disease worthy of recognition and further study. Given a patient with a rare and distinctive picture of dyspnea, cardiac area markedly diminished, apex beat difficult or impossible to discern, heart sounds very faint, remarkably low blood pressure and vital capacity, anemia, gradual loss of flesh and strength, costal breathing, absence of Litten's sign, a history of pleurisy, one sided or double pulmonary tuberculosis, particularly of the fibroid variety, and sometimes a record of treatment by artificial pneumothorax, one should look for x ray proof for a phrenocardiac syndrome and a hitherto hidden but enticing field for clinical and pathological research will be discovered.

CAUSES OF DIAPHRAGMATIC IMMOBILITY.

A diversity of opinion seems to prevail as to the cause of diaphragmatic immobility. It has been ascribed to paralysis of the phrenic nerve and the nerve endings in the diaphragm, to pressure of fluid in the pleural cavity, to adhesions which crippled the motion of that organ, and inflammation of the diaphragm, leading to degenerative changes and fibrotic thickening with loss of resiliency. Pathologists have added surprisingly little to our knowledge. Diseases of the diaphragm are usually dismissed with a few lines which have slight or no bearing upon puzzling problems in morbid anatomy. Only in very exceptional instances is the diaphragm examined with anything approaching thoroughness at autopsy. It has probably been more neglected than any other organ, which offers a new avenue for investigation. Owing to an inability to find opportunity for post-mortem study, it seemed that the only way to secure progress and promote research was by experiments on animals. A plan of procedure was outlined, based upon the following tentative deductions: Paralysis of the phrenic nerve, as a cause, was regarded as unwarranted from a physiological viewpoint. How the phrenic nerve escapes injury is difficult to explain in extreme cases of cardiac displacement, twisting and dense, binding adhesions to the pericardium. But it does, and the diaphragm did not in any instance assume the high position of paralysis. Weight of fluid induces a temporary disablement of a leaflet, but mobility may be resumed to a full or limited extent after the removal of downward pressure by aspiration or absorption. The amount of fluid and the length of time pressure is maintained, are not the chief etiological factors, as some have affirmed, and the diaphragm may remain mobile after pleurisy with effusion, of long duration, and frequent withdrawals of exudate. Adhesions contribute to fixity, especially in the region of the sulci, and contract the space in which the diaphragm moves along the inner and outer points of attachment, but they do not fully account for the complete destruction of all motion, particularly in the bilateral type where the sulci are plainly visible and increased in depth. Furthermore, if the lip of the base of the lung becomes attached to the diaphragm, it would not interfere with the rise and fall of the leaflet unless disease of the diaphragm was also present. The opinion was advanced, that morbid changes in the diaphragm offered the most probable solution and that adhesions would be found to be a contributory agency. The purpose of the research was to learn, if possible, first, the chief causative factor; second, if pleurisy in the animal would supply evidence to uphold conclusions based upon clinical observation; third, if experimental investigation should prove successful, to find methods of treatment more satisfactory than those now employed and essentially preventative in character. At the present time a preliminary report is presented, with the assurance that investigation will be continued.

The Rhinological Surgeon's Position in Diseases of the Maxillary Sinus and the Relation of the Antra to Affections of the Other Sinuses*

By HAROLD M. HAYS, M.D., F.A.C.S.,
New York

In the numerous papers which I have read before dental societies in the past, I have brought forward persistently the necessity of a closer relationship between the rhinological surgeon and the oral surgeon. When I speak of the oral surgeon, I include also the dentist of today, who has to make diagnoses of surgical conditions of the jaw. I tried to make plain to you that there are various definite relationships between diseases of the nose and throat and the teeth which made it often absolutely necessary that a diagnosis be made of a condition in a part foreign to the specialization in which a man generally works. It is also most difficult, unless the rhinologist progresses with the times, to be able to appreciate that there are lesions within the nose, for example, which are due directly to some oral condition; *per contra,* it is also difficult for the oral surgeon to appreciate that there are nasal conditions which may cause a great deal of trouble with the jaws or teeth. As an example of the former I may cite a recent case of a man, an old patient, who had come to me because of a nasal obstruction on the left side. This man had had a deviated septum corrected by me years before, with an excellent result and had had no trouble for five years, when he again had a nasal obstruction for which I could not account. Thorough investigation, which included the x ray examination, showed a cyst in the upper jaw which eventually proved to have eroded both the maxillary antrum and the floor of the nose, raising the mucous membrane of the nose so much that it was almost impossible for the man to breathe through that side. I referred the patient to an excellent oral surgeon who operated upon the cyst, with the result that his nasal obstruction entirely disappeared. So also the oral surgeon or the dentist will come in contact with patients, children particularly, who are suffering from various forms of nasal obstruction which he, perhaps, thinks are due to malformation of the jaw, principally a high arched palate. More thorough examination by the dentist will reveal the fact that the child has tonsils and adenoids or an enlarged inferior turbinate which is causing all the trouble. If he is aware of such pathological conditions, it is his duty, not only as a dentist, but as a man who is supposed to be alive to these conditions, to see that the patient is referred to the proper person for a more thorough investigation.

I feel that dentistry has arrived at the stage at last where it should be a part of medicine and, no doubt, as time goes on and more thorough researches are made, it will be necessary for any man practising dentistry to have an M. D. after his name so that he will be considered a specialist in a medical art rather than practising an art which is considered by many as foreign to medicine.

---

* Read before the Bergen County Dental Society (N. J.), March 10, 1922.

GENERAL ANATOMICAL CONSIDERATIONS OF THE ANTRA.

The antra are so situated that ordinarily they should give little trouble, as far as drainage is concerned, provided the normal opening is patent. It is a remarkable fact that Nature has arranged this drainage into the nose in such a way that it acts by syphonage. The opening of the antra, high up in the nose, in the region of the middle turbinate bone, necessitates the creation of a certain amount of suction in the nasal chambers before it is possible for any of the secretions from the antra to be evacuated. This opening is extremely small so it is no wonder that it becomes so easily closed off when there is an inflammation in the nose. The wall of the antrum is composed of heavy bone except at its lower portion, internally, where it forms the outer wall of the inferior meatus. In this position, the bone is extremely thin and may easily be punctured by a trocar so that it may readily be washed out. This thin wall has no particular physiological significance, but is of peculiar interest to the rhinologist who, so often, has to puncture the antrum and wash it out either with a trocar and cannula, or through a Lichtwitz needle. Of a great deal of importance is the location of the floor of the antrum. The floor may be on a level with the floor of the nose, but in the majority of cases it is decidedly lower. In other words, there is a concavity in the lowermost portion of the antrum, so that a certain amount of fluid may lie below the floor of the nose when any pathological condition in the antrum exists. This floor is made up of the maxillary bone inferiorly and comes in close contact with the teeth and as you are all aware, often some of the roots of the teeth penetrate through the antral wall and actually enter the antrum cavity itself. The lining mucosa of the antrum is also of importance. Usually it is made up of a fine thin membrane which is extremely sensitive, particularly in the region of the infraorbital nerve. This mucosa may very readily become affected or infected when any lesion in the nose itself occurs. Such inflammatory reactions in the mucosa may result in a thickening of the mucous membrane, to the extent that actual polypoid formation of the mucous membrane take place, without having any outside lesion to account for it. For example, an affection either of the maxillary bone such as a necrosis or a decay of the teeth may be present, secondarily affecting the antrum. I am so aware of the important part that an inflammatory condition of the mucous membrane of the nose plays, that frequently I do not feel that I am in a position to make a diagnosis of an acute antral condition, with the formation of fluid, because my transillumination shows that there is a shadow either on one side or the other. For it is possible that a thickened mucous membrane will show a darkened area on one side with no actual pus in the cavity itself.

I have already referred to the normal drainage of the antrum. One must realize the relationship of the various sinuses, which will be spoken about later, and also appreciate the fact that the small opening of the antrum is situated in such a position that it can readily be occluded by an engorgement of the mucous membranes in this region, particularly an engorgement of the middle turbinate bone: Where normal drainage takes place, the mucus either goes down the throat or is blown out of the nose into a handkerchief. No one realizes the enormous amount of secretion normally taking place until there is an actual change in the condition of the mucosa due to some infection of the nasal cavities or of the antrum itself. When such takes place, the thickening of the secretion is so great that it is impossible in many instances to expel it, and a plug of mucous or pus stops up the normal opening.

Pathological conditions of the antrum may be divided into the acute, the subacute and the chronic. The rhinologist comes in contact with the two former classes more often than he does the latter, but it may be possible that some of the latter cases may be due to a rhinological condition, though it is my opinion that the majority of the chronic cases particularly with the formation of thick pus, are due to some necrosis of the alveolar process or of the teeth themselves. The acute condition manifests itself by a neuralgic pain which radiates to the side of the head and a peculiar sensitiveness of the cheek bone. One must be careful to differentiate this from an alveolar abscess. In one or two instances I have had patients sent to me with a diagnosis of an acute sinus condition, where an alveolar abscess was manifest and would have been detected by the oral surgeon or the dentist readily. The differential points between the two are mainly these—in the alveolar abscess one notices a great swelling of the cheek and gingival fold, while in the majority of sinus cases there is no swelling to be particularly noticed.

The acute cases divide themselves into those in which there is drainage from the nose and those in which there is no drainage, the latter being an empyema of the antrum. If the drainage is profuse, that is, if a number of handkerchiefs have to be used throughout the day, one may be satisfied that proper drainage is taking place through the normal opening. On the contrary, if there is acute pain in the antrum, which is evidenced by every jarring motion of the body, or a certain amount of dizziness, one may consider that there is an empyema or a closed cavity in which fluid or pus is present. This condition may be diagnosed in numerous ways which will be mentioned. It is surprising how drainage can take place from an acute condition of the antrum, without manifesting any serious results as far as actual injury to the mucous membranes of the nose or the throat. Sometimes an acute condition may resolve into a subacute or a chronic condition which will evenuate into an actual pathological lesion of the mucous membrane of the antrum. There may be no symptoms until the patient lights up an acute cold, whereupon the cavity becomes closed off. One may consider these cases belonging in the subacute class, when a patient has a constant drainage from the nose or else is constantly reinfecting the mucous membranes of the nose in such a way that he is hardly ever free from colds. I have known of a patient who has had a continual dripping in the back of his throat or has had one cold after another, where a diagnosis was not made for a considerable length of time and eventually was cleared up when the antrum was drained properly. When it comes to the chronic antral conditions on the contrary, one may consider that he is dealing, in the majority of instances, with something outside the rhinological field. Although it is possible that a chronic antral condition may be associated with a chronic condition of the other nasal sinuses, it is my opinion that the majority of cases of chronic disease of the antrum arise from some necrosis in the jaw or teeth. I have rarely seen a chronic infection of the antrum, without an affection of the other sinuses if the causative factors were nasal. The affection may have started as a nasal condition but in the majority of cases some diseased condition of the upper maxilla is present and the diseased condition of the antrum itself can never be entirely eliminated until, either the teeth are properly attended to or the necrosis of the bone is taken care of in the proper way.

DIAGNOSTIC POINTS OF VALUE.

Among the various diagnostic points which must be considered, in order to determine an antral condition, may be mentioned the following, transillumination, x ray, suction, puncture and washing, exploratory invasion.

1. *Transillumination.*—In any rhinologist's office an instrument of the most importance is an intense light which allows of proper transillumination of the antrum. The transillumination may be performed by placing the light in the patient's mouth against the upper maxillary bone, having the teeth and lips tightly closed and then comparing the two sides. If the antrum is clear, and the bone is not too thick, one will be able to see a crescentric zone of light underneath the eye and sometimes he will be able to see the retinal reflex. Transillumination is of great value when it is negative but in a great many instances one is able to see a difference in the shadows of the two sides and sometimes almost a complete blackness on one side which will make him feel that an antrum affection is present. However, one can slip up readily, and sometimes even when an x ray checks up. I have washed out many sinuses, showing such manifestations, and have been unable to feel that there was any diseased condition within the antrum which warranted the interference which I had given. Even with the best transillumination outfits in the majority of cases an x ray picture will have to be taken in order to determine whether a diseased antral condition is present or not. Here again, let me warn you that one should never make a diagnosis of a diseased antrum because the x ray findings show that there is a cloudiness on that side. You must realize that there must be acute, clinical symptoms present which must be taken into consideration in conjunction with the x ray or the transillumination findings. I, as well as others, have frequently been misled by the x ray picture and today I would not consider that I was justified in attempting the exploration of the antrum, unless I had a thorough, clinical picture which would corroborate the x ray picture.

Sometimes the patient complains of pain on one side of the face, of an indefinite nature, and nothing can be seen in the nose. However, when the mucous membranes are properly shrunk up with cocaine and adrenalin, it may be possible to determine that there is an occlusion of the normal opening. With the application of such medicines, sometimes the plug in the normal opening will come away, particularly if suction is used at the same time. Suction may be obtained from an electric suction pump or the water suction apparatus. If the former suction is used, very frequently a certain amount of mucopus can be drained out of the sinus and a diagnosis of the condition made in that way. However, sometimes the plug in the normal opening is so tight, that it is absolutely necessary to explore the antrum by washing it out. This may be accomplished either by the trocar and cannula or the Lichwitz needle. The procedure for doing this cannot be detailed here. I have never seen any harm done by an exploratory puncture of the antrum, but I am indeed surprised at the number of times the washings are negative. I am informed by a number of rhinologists that there is hardly a day when they do not feel justified in washing out the antrum in at least two or three cases. Considering that my practice is as large as many of theirs, it is a surprising fact that we find it unnecessary to wash out the antrum, perhaps, more than once or twice a week. Where actual, acute symptoms are present, there may be only an inflamed mucous membrane and in such instances, exploratory puncture will relieve this tension within the antral cavity which, in itself, may be enough to allow the symptoms to subside. One may make an exploratory puncture in the thin part of the antrum wall with a Lichwitz needle—a valuable and painless procedure.

However, if one feels that there is actually something within the antrum which actually needs drainage, it is better to make a large enough opening so that it will remain patent for a few days. This may be done with any of the numerous trocars and cannulae on the market or may be made with the antrum chisel. It may be possible in some instances that the affection from which the patient is suffering is not due to actual pus within the antrum but is due to granulation tissue therein. This is more likely to occur in chronic cases. Within recent months, certain instruments similar to the nasopharyngoscope have been devised which can be inserted into the antrum, through a large enough opening, and one may inspect the cavity without any difficulty. However, if one makes an opening of that size, he is in a position to probe the cavity and get an idea of its interior. If the mucous membrane is in a polypoid condition, no amount of interference by the rhinologist, it seems to me, will be enough to clear up the condition. For it is my opinion that the majority of these cases are associated with dental infections, in one way or another. Therefore, it is frequently necessary to make an exploratory puncture through the alveolar border so that an examination under actual, ocular inspection, of the parts within, may be made. Such an opening does little, if any, harm and one is able to view the antral wall and to state exactly whether there is anything there or not. If nothing is found, it is a simple procedure to sew up the mucous membrane again and allow the bone to reform.

From what has just been said, it is often difficult to state just which cases belong to the rhinologist and which to the oral surgeon. I am of the opinion that it is often impossible to tell at one examination who is the proper specialist to take care of the case. Yet, one may draw a dividing line as follows: the majority of acute and subacute antral cases belong to the rhinologist, and this includes antral conditions which are associated with affections of the other sinuses. The majority of chronic antral infections which extend over a long period of time should be attended to by the oral surgeon or the dentist; at least, no interference should be attempted by the rhinological surgeon, until a definite opinion is given by a specialist in the other field. There is one other point of importance: if granulation tissue has been determined upon as being present in the antrum an opening in the inferior meatus of the nose, with irrigation and drainage, is not sufficient to allow of a thorough cure, mainly for the reason that in the majority of the cases the floor of the antrum is lower than the floor of the nose, and therefore one would have to depend upon getting uphill drainage. That does not mean to say, however, that the rhinological surgeon should not attempt an operation, like the Caldwell-Luc, but I feel that, with the more minute accuracy with which the oral surgeon is able to do operations under local anesthesia, such operations belong to him, rather than to the rhinologist.

I could cite a number of cases which I have referred to oral surgeons, which show definitely that the work that had to be performed upon the patient was work which should not be attempted by a nose and throat surgeon. Within the past few years I have had a few such interesting cases, the citation of one or two of which will suffice.

Case I.—The first patient was a man who had had a nauseating discharge from his nose which had lasted for a good many years. There was a small sinus above one of the molar teeth. After examining him thoroughly and determining that the antrum was diseased, I decided that he had better be attended to by an oral surgeon and therefore I referred him to Dr. Joseph Levy, who completely opened up the antrum and found it filled with an enormous amount of thick greenish pus and granulation tissue. The operation was thoroughly done, every part of the cavity minutely explored, with the result that when it finally closed up, the patient was completely cured. Now I feel that, if I had attempted to take care of this case, it would have been necessary for me to have infringed upon the field of the oral surgeon, for in the operation it was found that the roots of two or three of the teeth which penetrated the antrum were necrosed and part of the jawbone also showed necrosis. I feel that the attendance of an oral surgeon, in such a case, is not all that is necessary. The oral surgeon is in a much better position to perform any operation through the alveolar border. He is used to administering local anesthesia to these parts and is also in a position to remove necrosed teeth and diseased maxillary bone. Sometimes we come across anomalous conditions in which there is every evidence of an antral infection, and in such instances, even when the case is taken care of by an expert oral surgeon, no definite determination can be made as to the exact cause of the condition. This is particularly evident when on exploration of the sinus it is found to contain no granulations or pus. A recent instance will illustrate this.

Case II.—A patient came to me, complaining of a great deal of pain over one side of his face with severe headaches. He had been told that there were a number of diseased teeth. Examination of the antrum, by transillumination, showed it absolutely black. The other antrum was clear. This finding was confirmed by x ray pictures, and so I thought that it was necessary that his antrum be explored, preferably, by an oral surgeon. I therefore referred him to Dr. Theodore Blum, who, much against his wishes, removed a necrosed tooth and a small portion of the upper maxillary bone and then made a small window opening into the antrum.. He saw that the antrum was clear, but in order to definitely determine this fact he took away a great deal more of the wall and found that there was absolutely no lesion of the mucous membrane. Here was an instance in which there was definite evidence by transillumination and x ray that there was a lesion of the antrum, and yet none was found. How can we account for the fact that these two diagnostic aids led us astray? I cannot say. I felt that we were justified in going into this antrum and yet the finding was not sufficient to warrant our doing what we did.

What is the relation of the antrum to the other sinuses in the nose and what is the value of this relationship? The antrum has a definite relationship insofar that the normal drainage of all the sinuses takes place in a certain part of the nose, called the vicious circle. This is in the region of the middle turbinate bone. Here enter the openings of the frontal sinuses, the antrum, the ethmoid cells, particularly the anterior ethmoid cells, and some of the posterior and the sphenoid. If one has an acute affection of the mucous membrane of the nose, it is but natural that all the openings of the sinuses should be closed and it is a well known fact that once there is an inflammation of any of the sinuses, some inflammatory condition of the other sinuses will take place. Moreover, one may have an acute affection of the frontal sinus or of the ethmoid cells and the direct drainage may take place through the antrum so that it becomes infected. In such instances, the infection may change from an acute into a chronic one, but at all times the patient should be in the hands of the rhinological surgeon. One must make up his mind to take many things into consideration when he wishes to definitely determine the relationship of the antrum to various other sinuses of the head and to the jaws or to the teeth.

One fact, of great importance, is the determination of the amount of discharge through the nose, and another point of great importance is the determination of the causative organism. There are various organisms which, apparently, do very little harm within the nose which may create pus, but pus of a nonvirulent character. Such organisms may well be taken care of by thoroughly irrigating the sinuses, particularly the antrum, with some antiseptic solution. On the contrary, if one is dealing with one of the various streptococci or pneumococci, it is necessary for him to go further to eliminate the organism, and he will almost invariably find that if one of them is present, there is an infection of one or more of the other sinuses and that it is necessary to treat them at the same time.

It is almost impossible for one to realize that the normal secretions of the sinuses amount to about a quart of mucus a day, most of which is swallowed. One only gets an idea of the actual state of affairs when the character of the mucus is changed by infection and he either has to expectorate this mucus, which goes down the back of his throat, or he has to blow it out in a handkerchief. With our greater knowledge of the actual anatomy of the sinuses, and their various anomalies, it is possible for us to very often determine how much of a sinus is affected, how many of the sinuses are affected, and the effect of such infection on other parts. Of course, deductions are not always very definite or accurate, but they can be made in many cases, and in some of these cases in which infection is found, very little may be determined either by transillumination or the x ray or by the clinical findings. For example, in pathological lesions of the eye, certain cells of the ethmoid labyrinth are affected in such a way as to cause definite pressure upon the optic nerve, yet our examinations show absolutely negative findings. However, if the sinuses are properly opened up and what is called aeration of the sinuses is affected, it is surprising to see how quickly the eye condition responds to that opening up and how eventually the patient gets well. It frequently happens that a direct irritation, either of an antrum or of one of the sinuses, may cause reflex symptoms in other parts of the body which may be of a serious nature, and it is only after the elimination of the localized condition that one is able to determine exactly how much value may be placed upon the clinical evidence which is given by an affection of one of these parts.

It would be impossible to go into great detail of all the affections of the sinuses at a meeting such as this. I think I have been able to show you that there is a direct relationship between the work on the sinuses which should be performed by the rhinologist and that which should be performed by the oral surgeon or the dentist. In regard to treatment, it is only necessary to say that when it comes to the acute or subacute condition of the sinus, a thorough cleaning of the nose, with proper irrigations, will accomplish a great deal. Irrigations may be performed in numerous ways, the details of which are unnecessary at the present time. When it comes to the chronic antral condition, it is absolutely necessary that a proper opening up of the sinus be performed. It is a harmless procedure, in the majority of cases, although it may be a more or less painful one and the patient is far better off to have a thorough exploration of the sinus, in spite of almost negative findings, particularly if the symptoms are severe enough to invalid him a great deal of the time.

Case of Perisinus Abscess*

By J. COLEMAN SCAL, M.D.,
New York.
Adjunct Otolaryngological Department, Gouverneur Hospital.

Cases of perisinus abscess although quite common are of sufficient interest to warrant reporting. In this case the latent development and the disappearance of all symptoms immediately after operation were especially interesting.

Case.—J. K., aged fifty-five, single, laborer. Admitted to Gouverneur Hospital October 9, 1922, in the service of Dr. W. W. Carter.

For four months before admission the patient had suffered from severe pain and discharge from both ears. These symptoms gradually subsided until a few days before admission, when the region behind the right ear became swollen and caused severe pains in both the right ear and in the frontal region of the head. He had not consulted any physician until this time. He was admitted to Gouverneur Hospital for immediate operation.

The patient was a well developed and fairly well nourished man apparently suffering excruciating pain over the frontal region of the head and over the right mastoid. His eyes reacted normally to light and accommodation. The nose, throat and sinuses were negative. Temperature on admission was 98°, respiration 36, pulse 86. The blood examination showed leucocytes 16,000, polymorphonuclears, seventy-six per cent., lymphocytes twenty-four per cent.

The left ear showed a thickened drum with a large perforation and purulent discharge. No pain or mastoid tenderness was present. The hearing was not diminished.

The right ear showed a red, bulging drum with a marked sagging of the roof of the canal. There were three perforations in the drum, the largest of which was situated about the middle of Schrapnel's membrane. There was a scant, seropurulent, foul smelling discharge present in the external auditory canal. A marked pulsation was evident through the perforations. The mastoid presented a distinct edema and swelling over the upper portion, with tenderness at the tip. The ear was pushed forward. Hearing was diminished.

A simple mastoidectomy was performed. As soon as the periosteum was separated and elevated, pus gushed from two or three small broken down areas in the cortex. Pus and granulations were found when the mastoid was opened. The antrum was located, exposed, and found filled with granulations; but there was no pus present. The sinus was exposed from behind the knee to the horizontal plane; the thin covering of bone over it was soft and partly broken down. Removal of this thin bone revealed a perisinus abscess in the region of the knee. The sinus wall was covered with healthy granulations. The sinus itself was of a shiny bluish color and pulsating. As no symptoms of sinus thrombosis existed the interior was not disturbed. A section of the inner table of the bone was removed from the knee and the dura exposed. No epidural pus was found. The cavity was drained lightly with iodoform gauze.

---

*From the Otolaryngological Department of Dr. W. W. Carter of Gouverneur Hospital.

The postoperative course was uneventful. The temperature rose to 100.5° but dropped to 99° on the second day and then remained normal. The patient was allowed out of bed on the fifth day and discharged from the hospital at the end of the third week, the wound being healed and the ear dry.

950 Park Avenue.

Suicide Among American Physicians—Its Causes and Suggestions for Prevention*

By S. ADOLPHUS KNOPF, M.D.,
New York.

Certain of our medical and lay papers recently published some startling statistics concerning the number of suicides among professional men. In the United States during the year 1921 there were the following number of suicides: Physicians, sixty-nine; judges, fifty-seven; bank presidents, thirty-seven; clergymen, twenty-two; editors, ten; statesmen (members of legislatures), seven. Through the courtesy of Dr. George H. Simmons, the editor of the *Journal of the American Medical Association,* I have come into possession of statistics of suicides among physicians in the United States for the past ten years which reveal a startling situation. These figures are as follows: In 1912, 36; 1913, 43; 1914, 27; 1915, 44; 1916, 39; 1917, 31; 1918, 39; 1919, 38; 1920, 32; and 1921, 69. This means that the number of suicides among American physicians has increased over a hundred per cent. during the past year as compared with 1920. I have no explanation for this sudden increase, except perhaps that it is a delayed aftermath of the World War with its economical, moral and psychical disturbances. Whatever the cause may be, this sudden increase is certainly alarming.

It is really pathetic that among the members of the profession whose prime objects are to preserve life by protecting individuals and communities from infectious diseases, epidemics, and plagues, who as surgeons or physicians heal wounds, cure disease, comfort and console the suffering in mind and body, there should be the greatest number of suicides of all the professional classes! In a paper dealing also with the subject of suicides observed among physicians, Dr. S. Dana Hubbard, Director of the Bureau of Publicity of the New York City Health Department, who has investigated a large number of suicides, says that he does not wish to be unfair to his professional brethren, but that unfortunately a thirty years' experience in the practice of medicine has furnished a number of opportunities to him of seeing professional confrères terminating their lives too abruptly. He then adds the following significant statement: "Many of these cases were masked officially for one reason or another so that the truth was hidden; nevertheless the fact remains, when the truth is known, that selfdestruction was the cause and not that which was furnished by the death certificate."

In a recent letter to the New York Medical Journal the same author, in giving virtually the same statistics of suicides among physicians as Dr. Simmons, deplores this frequency of suicides, and says: "This record seems to indicate that the occupational strain is greater in medicine than in any of the other professions. Should not our scheme of medical practice, as relates to hours and relief, be revised and, if so, how should this be accomplished?"

My good friend Hubbard will forgive me if I seem to differ with him when I say that strain is not the only cause of the mental attitude which prompts this large number of colleagues to take their own lives. Many young men enter the profession with exalted ideas of obtaining wealth and fame. They should be reminded at the outstart that the one who has decided to choose medicine for his life's calling must not do so with the idea that it will be easy to climb and to become a great surgeon or internist with a fabulous income. Only those who enter the ranks with an earnest desire to serve, to work for the good of others with no thought of selfaggrandisement or gain of wealth, and to be content to make a comfortable living and cling to the highest ethical standard, will really achieve success. To those who have less high motives, who look upon the medical profession merely as a business proposition, there will be bitter disappointments and disillusionment.

Among those who cannot realize their unfitness for the calling of a physician and have not the courage to take up some other pursuit, there will always be some who may enter illicit practice, and because of this they may even be financially successful; then something happens and, facing exposure, they abruptly finish their existence.

Suicide statistics always reveal that the unmarried predominate over the married. Personally, I know any number of brilliant surgeons and physicians well able to support a wife and family, who remain single and say as an excuse for this that they have no time to get married. Some use the poetical phrase that they are married to their profession. This is all well and good, but no profession can replace the comforts of a home, the devotion of a loving wife, or the laughter of happy children. Therefore my advice to the young doctor would be as follows: Get married as soon as you can establish a home with an average degree of comfort. It does not cost so very much more than living alone. Carry an insurance according to your income. Live as normal, healthy, and sanitary a life as you would wish your patients to lead.

---

*Read before the Society of Medical Jurisprudence at the New York Academy of Medicine, November 13, 1922.

A dingy, cheerless, badly ventilated, dusty and untidy reception room and office is depressing to the physician as well as to the patient. The reverse condition, a neat, bright, cheerful, and well ventilated office is good for the mental attitude of physician and patient alike.

Have yourself examined every year by some competent colleague so that any insidious trouble may be discovered and treated before it is too late.

Selfpreservation is essential for the physician as well as for anyone else. While he should never neglect his medical duties for superficial social functions, let him enjoy sound social life and participate in all that is good and uplifting and all that will cheer him in his work. Let him attend medical meetings, but not associate exclusively with doctors where "shop" as a rule is the only topic of conversation. Among his recreations should be some which demand at least a few hours of outdoor life during the week.

Now as to the direct prevention of strain! Let us begin with the general practitioner, the one who is robbed of the greatest number of hours of sleep during the year by confinement cases, and who therefore has the greatest physical and mental strain imposed upon him. How can he arrange the number of confinements so that they will not tax his strength to the utmost as they sometimes do? Let two or three colleagues come to an understanding to arrange the confinement cases among themselves in such a way that they will be equally distributed and not cause the breakdown of one or another colleague. When a woman engages a physician to attend to her confinement, let the physician make it clear to her that if he cannot come at the time, Dr. A or Dr. B will attend to her. It must be obvious that through such an arrangement no one will suffer, but the hard working physician will be benefited.

The general practitioner with a large office practice should bear in mind that he cannot do justice to his cases nor to himself if he sees too many patients at a time, and that he cannot diagnose difficult cases when overtired. The latter cases should be received by special appointment outside of the office hours.

It is an honor to be attached as attending physician or surgeon to a hospital; but it is unwise and unfair to accept appointments as visiting physician or surgeon in many hospitals. It is unwise because the attending surgeon or physician puts on himself too great a strain by too much hospital service. It is unjust toward other colleagues equally able, who for one reason or another have not received a hospital appointment, and lastly, and by no means least, it is unfair to the hospital patients who cannot get the care and attention they are entitled to when the physician who sees them is himself overtired physically and mentally.

One fact which in my opinion is perhaps the direct cause of more suicides than anything else is the use of habit forming drugs such as morphine, cocaine, and heroin. A few years ago, beside my tuberculosis service at the Riverside Hospital there was established a large service for the cure of drug addicts under the direction of Dr. T. F. Joyce. There were always a few physicians among them. I had many a chat with Dr. Joyce relating to the primary causes of drug addiction in physicians. It had been found that it was almost invariably the overstrain resulting from sleepless nights on account of confinement cases succeeding night after night, combined with attending to a large general practice during the day, which prompted the taking of drugs as stimulants.

To remove all possible doubt concerning the accuracy of this statement, let me read to you from a letter received from my friend, Professor Alexander Lambert, of Cornell Medical College, who has perhaps the largest experience of any one in this city in the treatment of drug addicts: "Of 1,700 drug addictions in private practice of my own experience or of my own knowledge, 405 have been doctors. The greatest strain has come from worry and overwork, 163 coming under that heading. They broke in the late twenties, around thirty and before forty years of age, in the vast majority; i. e., 165 of the 405 when they were building up their practice and trying to swing it all without assistance and under the weight of responsibilities with but little savings."

Before a man gets into such a physical and mental condition he should be told: Rest when you are tired; refuse night calls; get away from work entirely for a day or two or more if necessary, but never, never seek relief in drugs which you would not prescribe for your patients, and bear in mind that no matter how strong a will power you may possess prior to the habitual use of morphine you can no more control your desire for the drug once the habit is acquired, than the least intellectual or the least moral morphine, cocaine, or heroin habitué.

To the young medical or pharmaceutical intern, who for curiosity's sake takes a few snuffs of cocaine or thinks he can safely experiment on himself with other narcotics too strong a "Don't do it" cannot be pronounced. In many cases of habitual addiction, particularly when the victim is a physician who has no difficulty in getting all the narcotics he wishes, the doses are constantly increased in order to get the desired effect, until an overdose accidentally taken leads to a fatal result. The thought that he may never be able to master his craving also often leads the physician-habitué to the taking of an intentional overdose. Nevertheless, even the chronic user of narcotics of no matter what kind, need no more despair of a complete cure than the chronic alcoholic, if he is only determined to cooperate with the physician in whose care he has entrusted his case.

Moments of regret and an ardent desire to get rid of the degrading and life consuming habit are sure to come and the sooner this happens the better. When these moments do come, then is the time to seek the advice of a colleague familiar with the methods to cure drug addiction. In some cases it may perhaps be better to enter a special institution for that purpose. If the patient fears that his being an inmate in a local hospital or sanitarium might become known in his community, let him apply to the editors of any reputable medical journal, or to the chiefs of the health departments of any of our big cities, and I am sure any one appealed to will gladly supply the inquirer with a list of reputable institutions where the unfortunate victim will have the best possible chance to obtain a thorough and lasting cure.

What are the psychical causes which may depress the physician to such a degree as to create a desire to finish his earthly existence? When the sympathy which he should always have for his patients develops into a morbid sentimentality; when he is too much affected by the hopelessness of some cases and cannot reconcile himself to the fact that what cannot be cured must be endured; when he cannot realize that even with all our advances in medicine and surgery there will be always cases which do not yield to treatment; and when he broods over such cases, there is danger of his mind becoming affected and of his growing morose and despondent. A wrong diagnosis with sad consequences, or failure in an operation, are serious matters, but not enough to cause the sacrifice of a second life. Every physician must strive to develop a sound philosophy of life. He must realize man's inability to know all the whys and the wherefors and that to do the best one can under all circumstances, is the only remedy. Life has its pains and also has its pleasures, but above all life is a duty, and duty well done will find its own reward.

Perhaps one reason why the medical profession has the sad distinction of furnishing the greatest number of suicides among professional men is the lack of a spiritual conception of life, a tendency to disbelief in all things spiritual, and an acceptance of the erroneous idea that to do away with the physical existence ends all. All religions teach the immortality of the soul, the existence of a physical and of a spiritual being, and the continuity of life as an entity. Those of us who have witnessed many deathbed scenes will long since have abandoned the medical student's conception of death. To many of the young followers of Æsculapius the dissecting room is the last resting place of most and would be the finishing episode of the existence of all of us, if we should have no one to take care of our "mortal coil."

The great physician-poet Oliver Wendell Holmes was once approached by one of his students during a lecture in the dissecting room with the following query: "Dr. Holmes, if there is such a thing as a soul please show me its location." The great anatomist's reply was, "Only a fool will look for the soul with a knife." Dr. John H. Finley, in a recent article entitled A New Spiritual Century in Contrast with the Old, speaks of a prominent American chemist who, at an international meeting of chemists last year, said that there was something that could not be explained on a purely materialistic hypothesis. Another eminent scientist and at the same time one of the greatest physicians of the Anglo-Saxon race, Sir William Osler, Bart., Regius Professor of Medicine, Oxford, recognized authority on internal medicine throughout the civilized world, who died a few years ago at the age of seventy, a victim of too strenuous work on behalf of the sick and wounded soldiers, during his lifetime was considered an honest agnostic by many of his admirers. And yet in his address on "Science and Immortality" at Harvard University in 1904, we read, "Rather be mistaken with Plato than be in the right with those who deny altogether life after death, and this is my own *confessio fedei.*" Among his effects the following note was found which he had penned a few days before his death: "Dear Friends, the harbor is nearly reached, after a splendid voyage with such companions all the way, and my boy waiting for me." His son, Lieutenant Revere Osler, had made the supreme sacrifice in the World War, and Sir William then felt sure to meet him. He had become convinced that physical death was not the end of conscious individual existence.

It is perfectly rational to believe (and with many the belief is so strong as to amount to conviction) that death does not end all, and that those who voluntarily end their physical existence must experience infinite regret for not having been brave enough to have kept on battling. Psychology teaches and psychologists have demonstrated that the mind of one individual can control that of another, not only in the hypnotic but also in the wakeful state, and even without a tangible medium of transmission—speech, writing, or signs. Each mind represents an individuality different from that of another, that is to say, an entity. This entity is demonstrated in hypnotism, psychoanalysis, and that wonderful phenomenon called telepathy. This personal self is also felt by all thinking people in their daily lives. As an entity it cannot perish or disintegrate but must persist in its existence; for the individual soul there is no "Nirvana" (going up into a great oneness or nothingness) where all its past can be forgotten.

The attempt has often been made by kindhearted philanthropists to invite those who are despondent and heart sick and ready to finish their earthly existence to come to them and seek counsel and advice, and in a number of such instances a tragedy has been averted. There is an organization in existence in this city which has this unique mission and operates under the name of "The Save-A-Life League" with headquarters at 309 West Fifty-seventh Street. Whether or not the establishment of an institution or bureau for this purpose would be helpful to prevent our despondent medical brethren from resorting to suicide, I am not prepared to say. If some one in the profession with greater world wisdom thinks such an enterprise feasible, I will gladly serve under him. In the meantime, let all those who are sad in heart, depressed and despondent, take comfort and rest assured that if they will follow my humble suggestions for the prevention of despondency, they will surely see a brighter vision and better prospects for the future.

We must speak of one other cause which has led quite a number of physicians to commit suicide, and that is financial failure and ruin because of stock speculation. Unscrupulous brokers with get-rich-quick and high interest schemes usually make their attack first on the medical profession. They know that the average doctor has no business sense and no idea of the stock market, and as a rule he is considered by them as an easy mark. His mail is laden with offers of all sorts of sure and rapid methods to increase his wealth by the purchase of stock; mining, oil, automobile, or other kinds. He is visited or phoned to by glib tongued brokers and not infrequently becomes their victim. As it happens so often, a seemingly considerable sudden gain skilfully brought about by dishonest means makes the physician think that he will do better by speculating than by practicing medicine. His mind is no longer on his work and he begins to neglect his patients. The outcome of it all is alas too often the loss of all the savings and an accumulation of debts resulting from stocks bought on a margin. Realizing a dark future and inevitable ruin, altogether too many splendid colleagues have ended it by an overdose of the easily accessible narcotic. The prophylaxis in such cases is plain. Stay away from the stock market, invest your savings in securities which are secure even if they bring only five or six per cent. In other words, accumulate slowly but surely and you will be happier in the end.

The thought of suicide often enters the mind when there is fear that there will be no home and comfort of life when the individual is no longer able to earn and when circumstances beyond control have prevented any saving for maintenance in old age. This happens occasionally and more often perhaps among medical men than becomes generally known. To prevent those of our colleagues from becoming despondent and rushing off to end their existence, who often in spite of years of labor have not accumulated enough to assure them a carefree existence at an age when they can no longer work, let us who are in happier and more comfortable circumstances unite to establish a home for homeless, poor, and aged physicians where they may finish their days in peace and comfort. If married, they should be allowed to bring wives with them. To do all that can be done to make them happy and contented should be the aim of us who are still in the prime of life and able to help. To make the inmates of such an old physicians' home feel that they are not objects of charity but are entitled to what they receive, a society to which each member of the American medical profession might contribute a small amount annually, say one dollar, which would mean one hundred thousand dollars or more a year, might very easily be called into life. This, of course, should not exclude any generous donor who might wish to contribute a substantial sum toward a permanent endowment fund. Either the American Medical Association, the American Congress of Physicians, or some other national medical body should be made the depository or guardian of such a fund.

Such a fund and home for New York physicians has been already established and it owes its inception to Dr. W. Freudenthal, Dr. Robert T. Morris, and other prominent members of the New York medical profession. No doubt several of such homes in various sections of the country would be needed, but all should be under the supervision of an authorized and elected body of leading medical men of the United States.

I have reason to believe that even among the grateful patients of means there are many who would gladly give help in such a noble and worthy work of justice, and I know that many poor would just as gladly give their mite, but this of course we would not wish to accept. We do not ask for charity. I do not like the word in this connection. Every doctor does his share of charity in his practice and it would be only a just compensation for the innumerable services he has rendered without pay to the sick poor and thus to the community. He should be assured of an existence without care and anxiety when no longer able to work by reason of old age or infirmity. Assurance that if he is but true to his calling, a grateful public and his well to do confrères will see to it that he shall not be in want, homeless or friendless when old age comes on, no matter what misfortune may overtake him, will surely prevent the doctor from thinking of selfdestruction and shortening his career by a rash act.

We may not always realize it, but our beloved profession stands as a whole in high repute in the eyes of the public and many are the prayers and the tributes which come from grateful patients who duly appreciate the physician's calling and the services he renders to suffering mankind. Let him who is despondent because he imagines that all his efforts are in vain and that the physician's life is not worth living, read the beautiful tribute recently pronounced by no less a man than the Hon. Alton B. Parker, formerly Chief Justice of the Court of Appeals of the State of New York, who says: "Where will you find another man to match the average doctor? He lives the true altruistic life, devoting himself unreservedly to others. His skill and time are yours on the shortest notice, in the blackest hour of night, and in the worst of weather. His devoted unselfishness, ready sympathy and healthy good humor but increase his gray hairs. I, for one, expect to find a neat M. D. shingle decorating very many of the more palatial Heavenly Mansions on Good and Faithful Avenue."

In an admirable treatise on Suicide, John Rice Minor, Ph. D. (1), says: "The person who commits suicide dies because his mind is unable to make a satisfactory psychic or social adjustment to his environment." According to information kindly furnished me by Dr. Louis I. Dublin, the statistician of the Metropolitan Life Insurance Company, there were 9,000 suicides in the registration area, which would mean not less than 10,500 in the whole United States in one single year (1920). If we add to this number the many cases which are not reported officially as suicides but where, for various reasons, other causes of death are given, we may well feel alarmed. As physicians who are called upon to help a mind diseased as well as to alleviate physical sufferings, should we not strive in this age of great humanitarian efforts and social progress to stop the increasing deathrate from suicide among our own and other professions and among the people at large? Let us direct our efforts to that end. To save a life from selfdestruction is as great an achievement in the physician's calling as to save a life from a deathly disease by medical or surgical skill.

The Significance of the Protein Skin Reactions in Bronchial Asthma*

By M. MURRAY PESHKIN, M. D.,
New York.

The voluminous literature contributed to the subject of bronchial asthma studied along the lines of protein sensitization, has tended to create considerable confusion, particularly when one attempts to analyze the varying results obtained from the methods of procedure and the interpretation of the reactions. In the past five years considerable progress has been made; much, however, remains obscure for the surface has been scarcely scratched. No thesis on this subject can be considered complete unless mention is made of such pioneers as Schloss, Walker, Cooke, and Vander Veer, each of whom has worked along his own original line and has thus blazed a separate trail.

The purposes of this paper are:

1. To discuss only those cases of bronchial asthma exhibiting cutaneous reactions above the control.

2. To try to arrive at a clearer conception of the reaction in its relation to symptoms.

3. To emphasize the value of performing a complete series of food, epidermal, pollen, and bacterial protein tests in every case presenting itself for diagnosis.

4. To emphasize the importance of correlating the skin findings with a detailed history and a thorough physical examination as will be outlined.

5. To show that the wide range of differences in percentages of reactions depends upon many factors.

In order to clarify our ideas regarding the etiology of asthma and to avoid adding to the existing confusion, it becomes essential to lay down certain basic requirements, at least one of which must be fulfilled, before we can assume that any protein is etiologically important in a given case of bronchial asthma. Thus, sensitization must be demonstrated by a local cutaneous reaction; the symptoms must be relieved or greatly improved upon withdrawal of or by treatment with the protein, as the findings may indicate. An attempt should be made to show that the patient has come in contact with the suspected protein.

We do not deem it wise nor always safe to subject a sensitive person to a subcutaneous injection of the offending protein in order to demonstrate cause and effect. This experiment is not without possible serious or even dangerous consequences. Several deaths have been reported and deaths are known to have occurred that were not reported. It is well known that every sensitive patient has acquired a certain degree of protein tolerance and that the finding of a cutaneous reaction does not necessarily predicate symptoms. Then why break down tolerance by experimental means contributing other etiological factors to the existing asthmatic state? It seems to us more rational to withdraw the offending protein, or if this method is found impracticable or impossible then institute specific desensitization and observe results carefully.

Bronchial asthma exhibiting protein reactions above the control may well be classified into the following main groups:

1. Cases of asthma occurring during infancy and childhood only.
2. Cases in adults with onset of asthma dating back to infancy or childhood. A. Investigated and treated before the age of forty. B. Investigated and treated after the age of forty.
3. All cases with date of onset following the period of childhood and up to forty years. A. Investigated and treated before the age of forty. B. Investigated and treated after the age of forty.
4. All cases with symptoms of asthma becoming manifest after the age of forty with or without organic changes.
5. Occupational group.
6. Accidental passive anaphylactic group.

The preceding gross classification is further divided into the following etiological sensitizations:

1. Food.
2. Epidermal and dust proteins
3. Pollen.
4. Bacteria.
5. Drugs.
6. Therapeutic animal sera.

The procedure employed in the search for an etiological basis in bronchial asthma involves a detailed history, physical examination and cutaneous protein tests, each inseparably dependent upon the other.

The importance of securing a proper history can not be emphasized too strongly. Commencing with the age of onset, it must be definitely ascertained if complete relief followed a typical bronchospasm and whether or not it was associated with nasal or eye symptoms. The season of the year, the effect of food or internal medication and exposure to domestic animals must all be noted. A history of repeated attacks of recurrent bronchitis or rhinitis with occasional wheezing often points to bacterial infection. From this point it is most advantageous to carry the patient along in his history to the latest attack, because the early attacks bear a definite relationship to sensitization. The present age, frequency and duration of attacks, effect of environment, change in residence or occupation, should be noted; inquiry made about the pillows, covers and mattress, and if changed what the noted effect is upon the asthmatic attacks. In fact, anything in the home of protein nature must undergo careful investigation.

Some attacks definitely follow an acute infectious disease, such as pneumonia, influenza, and occasionally the acute exanthemata, most commonly measles. This type of asthma is frequently relieved by a change in climate. It is not uncommon to observe absolute freedom from all bronchial symptoms following an acute infectious disease. One of the most severe cases of asthma, of three years' duration, having three to six bronchial spasms daily requiring injections of a total of one dram of a one to one thousand solution of adrenalin chloride in twenty-four hours, occurred in a married woman aged thirty. Her asthma proved refractory to all forms of treatment. She prayed for an acute lobar pneumonia to set in, a previous attack having given her complete relief from asthma for two months.

---

*Read before the Yorkville Medical Society, New York, April 17, 1922.

A history of eczema in childhood, especially during the nursing period, strongly suggests food sensitization. Contact with certain individuals may induce or aggravate an attack of asthma. A married woman aged thirty-eight, living in the country, gave a definite history of attacks when in the presence of her neighbor who was a teamster. When skin tests revealed marked reactions to horse dander, she then recalled becoming severely ill when riding in a horse drawn vehicle.

An interesting case is that of M. B., an eight year old girl who suffered during the last four years from bronchial spasms whenever she visited a chronically ill maternal grandmother. The mother revealed upon close questioning that the child found relief in her own home, in which she never remained for more than a week. A strong reaction to rabbit hair caused search to be made in both homes, when pillows made of rabbit hair were found in the grandmother's house only. The removal of these has resulted in freedom from all attacks for the past four months.

A thorough physical examination is essential. Search for organic or structural changes, endocrine dysfunctions, gastrointestinal disturbances and for focal infection, must be made. The association of nasal obstruction and accessory sinus infection with many early and advanced cases of asthma is important and must be treated. However, many cases such as spasmodic rhinorrhea and sneezing, the so-called, and, perhaps, illnamed, vasomotor rhinitis and the noninfective cold, seem to justify the assumption that such phenomena are the local manifestations of some general state. A patient may be sensitive to several proteins and yet the attacks follow other conditions, such as fatigue, worry or changes in weather. Such multiplicity of excitants call for a search for some basal condition responsible for the susceptibility. The blood chemistry may give the only clue in some cases. Low calcium in the blood, corrected by intravenous injections, has cleared up some resistant cases.

Our experience has taught us that in order to study asthma properly from all viewpoints it becomes necessary as a routine practice to include all possible available food, epidermal, pollen, bacterial and dust proteins in every case, in any event not less than a hundred tests to a case. The cutaneous test is exclusively employed. All proteins we employ are prepared by the methods and under the supervision of R. P. Wodehouse. The variously recorded results of the skin tests are at times difficult of analysis. The explanation for these differences and wide range of percentages depends chiefly upon the fact that the proteins used are differently prepared; and the reading of the reactions are differently interpreted, due to lack of standardization and differences in the personal equation of the observer. The age, age of onset, environment, nationality, occupation of the patient and the number of proteins employed for testing must all be carefully considered in the final analysis. Most reports include hay fever and hay asthma cases, which we believe serves only to distort a correct analysis of the relative frequency of protein sensitization in bronchial asthma.

Sanford (1), employing the Walker technic, reports positive cutaneous reactions in only twenty-five per cent. of the eight hundred cases studied. Sterling (2), testing with food proteins only, found one positive case in a series of twelve asthmatics.

Cooke (3), in a careful study of a hundred cases of asthma tested by the intradermic method, found forty-three per cent. with multiple sensitization; thirty-one per cent. reacted to the pollens of early hay fever and thirty-one per cent. to the late hay fever. Only nine per cent. reacted with sachet, forty-four per cent. to animal dander, and thirty-four per cent. to one or more up to twenty food reactions; three per cent. showed distinct foci of infection; thirty-three per cent. had a complicating simple bronchitis, and six per cent. a clinically demonstrable tuberculous infection with symptoms of a true bronchial asthma.

George Piness (4), utilizing the Cooke technic, in a study of 150 cases, determined the etiology in from forty-seven to fifty per cent. of the cases. Multiple sensitization was common, especially in the food and pollen group. He found nineteen per cent. sensitive to the animal group, twenty-eight per cent. to foods, fourteen per cent. to the bacterial group, and twenty-six per cent. to the early and late pollens.

Walker (5), in a classical study of four hundred cases, found 191, or forty-eight per cent., gave positive cutaneous reactions and more than fifty per cent. of these were sensitive to more than one protein. A summary showing four fifths of the patients whose asthma began during infancy were sensitive; two thirds of those whose asthma began during childhood were sensitive; one half of those whose asthma began during young adult life were sensitive, none were sensitive who began after middle life. Thus, as the age of onset of asthma increases, the frequency of sensitization decreases. The following results have been taken from a study by Walker (6) of over six hundred cases. Of the total number of patients studied, positive reactions to the protein groups were obtained as follows: Seventy-four patients or twelve per cent. to food; sixty patients or ten per cent. to bacteria; one hundred patients or sixteen per cent. to animal emanations; sixty-six patients or eleven per cent. to pollen, thus finding three hundred patients sensitive of the six hundred cases studied.

FOOD PROTEINS AS THE CAUSE OF ASTHMA.

The chief offenders of the foods are the cereal grains, mainly the wheat grains. Next in order of frequency are rice, corn, rye, oat, and barley. On the East Side of New York where rye bread is most commonly used, rye sensitization in our experience ranks second to that of wheat. It is generally recognized that the greatest percentage of food reactions occur during infancy and childhood, being more numerous in infancy. Next to cereal grain, eggs and milk in the order named are the most common offenders, and with the succeeding ages of onset the frequency of sensitization to cereals, eggs, and milk is much less than for other foods such as fish, meat, and potatoes. In asthma developing after the period of childhood food plays a minor rôle.

Of 648 cases of asthma examined by Rackermann (7), nineteen cases or three per cent. were due to food sensitization, the patient's symptoms being definitely relieved when the offending foods were eliminated from the diet. Eleven of these nineteen cases occurred in children.

EPIDERMAL PROTEINS AS THE CAUSE OF ASTHMA.

This type of sensitization in conjunction with organic dust is responsible for more cases of asthma than any of the other protein groups. More than half of the epidermal sensitizations are due to horse hair and dander alone. Most patients giving a history of onset between the ages of two to ten and in those giving positive reactions past that age the trouble could usually be traced to occupation. Much less frequently cat hair and chicken feathers will cause asthma. Occasionally it is caused by sheep wool, cattle hair, camel hair, parrot feathers, and other foreign proteins. These can usually be detected by a careful investigation into the history and environment of the patient. From our observations chicken feather sensitization is uncommon in Jewish patients because it is rarely used for pillows or feather beds. When present it usually can be traced to occupation. However, goose and duck feathers are commonly used and give relatively frequent sensitizations. It is most interesting to note that dog hair is the least common cause of bronchial asthma.

Ratner (8) recently reported eight cases of rabbit hair asthma in children and points to its great practical significance, which has not been heretofore emphasized. Our results in the Children's Clinic (9) of Mt. Sinai Hospital, point to rabbit hair sensitizations as the most common epidermal protein associated with asthma. In every case except one in a series of twenty children studied in the clinic and in private practice, rabbit hair was found in the pillow or mattress upon which the patient slept. Commercially rabbit hair finds an open and ready market because it is inexpensive. Upon personal investigation we were surprised to learn how general is the use of rabbit hair in pillows and mattresses in the poorer homes. Over ninety per cent. of the cheaper grade of furs sold under various names are made of rabbit hair.

A case in illustration is that of a boy, J. R., aged twelve, with onset of asthma at two and a half years, duration of attacks from one to four weeks. After the age of five he began gradually to improve and at the age of eight was entirely free of all attacks. In July, 1921, after an interval of complete freedom from asthma for three and a half years, while in the country he suffered a severe attack when in bed but a short while. The following two weeks he seemed apparently well during the day but coughed and choked during the night, his sleep being very much disturbed. His condition cleared up a few days after his return to the city in August, and he enjoyed apparent health until the early part of January, 1922. Then the cough and wheezing returned, accompanied by slight asthmatic attacks occurring at night but somewhat improved during the day. He was tested against 110 food, epidermal, bacterial and pollen proteins, giving positive reactions to rabbit hair and Streptococcus viridans and doubtful reactions to beef, chicken, strawberry, cheese, celery, and duck feathers. Investigation revealed that the pillow in the country was made of rabbit hair and a recurrence of symptoms was attributable to a pillow, which proved to be made of rabbit hair. On February 7, 1922, this was removed from his room and he has remained well since, except for the few following days while recovering from a simple secondary bronchitis.

POLLEN AS THE CAUSE OF ASTHMA.

The spring and fall type are the two well known groups causing pollen asthma. The spring type is due to the pollen of timothy or red top and in most patients orchard and June grass are also found. Only occasionally does asthma result from exposure to the pollen of trees, shrubs, and flowers. Pollination begins about the middle or end of May and continues to the middle of July.

The fall type of pollen asthma is the most common form. The pollen season commences about the middle of August and terminates toward the latter part of September or until frost appears. The asthma usually begins between August 30th and September 6th, when it is most severe. The pollens causing sensitization are the short and giant ragweed, sunflower, goldenglow, dahlia, and corn. The ragweed is the chief offender.

In both types of pollen asthma, hayfever symptoms start with the onset of pollination. Occasionally pollen asthma is present with practically no nasal or eye symptoms. The fall type causes more intense asthma and protein intoxication. The continuation of asthma after the pollen season is due in most cases to a secondary bronchial infection, often accompanied by a nasal accessory sinus catarrh. Some cases of postseasonal hay asthma cease to have any paroxysms after a few desensitizing injections of the offending pollens. The asthmatic spasms are evidently due to the pollens in question as the exciting factor because improvement or relief is affected after treatment. Sterling (10) believes that patients sensitive to these pollens cannot throw off the protein intoxication when once they come in contact with it, and that state is kept up by some patients throughout the year and in others irregularly throughout the year. The spring type responds to pollen treatment more readily and with better results. The ideal treatment should include all pollens to which a patient is sensitive. In beginning the administration of pollen extract great care should be exercised not to give a dose large enough to break down the patient's initial tolerance. The succeeding doses are rapidly increased and as much pollen injected as can be tolerated, just keeping within the limits of a general reaction.

BACTERIA AS THE CAUSE OF ASTHMA.

In this branch of study much disappointment is generally expressed because most observers report few immediate positive skin reactions and the results from autogenous vaccine treatment have been equally as unsatisfactory. Many observers have entirely discarded the use of bacterial proteins in the routine performance of the skin tests. This is indeed an admission of the apparent uselessness and lack of faith in its employment as an aid in the search for an etiological factor in bronchial asthma. Up to one year ago we were in sympathy with these views.

Sanford (1) reported not a single reaction in 365 tests to Staphylococcus pyogenes aureus and albus.

Walker, Rackermann, Piness, and others, however, have demonstrated the value of employing bacterial protein skin tests in asthma, the results being confirmatory. The protein of Staphylococcus pyogenes aureus is the most frequent cause of bronchial asthma, that of Streptococcus hemolyticus, Staphylococcus pyogenes albus and Streptococcus viridans occur in the order given. Occasionally one finds a patient who is sensitive to the proteins of Micrococci tetragenus, citreus and catarrhalis, to the diphtheroid bacilli, Streptococcus nonhemolyticus and to the pneumococcus. Probably any type of bacterial protein may cause asthma. Goodale (11), who was the first to use bacterial proteins in the skin tests. obtained similar results.

Many patients that came under observation were considered clinically asthmatic bronchitis. These nonsensitive patients were especially studied for delayed bacterial reactions which were observed from six to seventy-two hours after the tests were performed. The type and size of the induration, the time of its first appearance, the period of maximum development and the required time for the reaction to disappear, were factors carefully noted. The induration and erythema is not very much unlike that seen in the von Pirquet reaction and it is classified in a similar manner, that is, from one to four plus. Some of these delayed reactions first described by Walker resembles a mild infection, the pus proven to be sterile. Positive delayed reactions were obtained by repeated testing against bacterial proteins in the nonsensitive and socalled asthmatic bronchitis patients. The great amount of routine work is more than compensated for by the ability to help some of these apparently hopeless sufferers. The results thus far observed are encouraging. The publication and scope of the work is withheld at this time in order that the observations can be properly checked and the results followed over a period of time.

Walker (12) and Rackermann (13) have reported excellent results from vaccine treatment in patients demonstrating an immediate or delayed reaction. Sicard (14) found the streptococci to be the most prevalent in asthmatic sputa and autogenous vaccine treatment yielded very favorable results. Babcock (15), Hutcheson and Budd (16), are strongly in favor of vaccine treatment. Vaccine made from the whole bacterial body of the sensitizing organism as determined by the skin test, is used in the specific treatment of bacterial asthma. The whole bacteria is employed, because the aim is to desensitize as well as immunize against infection with the same organism.

A case in illustration is that of H. C., aged thirty-three, first seen in November, 1919. Occupation, environment and physical examination could not explain the etiology of his attacks. In February, 1919, he contracted an acute bronchitis persisting for two weeks. This was followed by bronchial spasms usually occurring about 4 a. m. daily. A rhinologist referred him with the assurance that there was nothing in the nose or accessory sinuses responsible for the asthma. Four months' treatment by a gastroenterologist, believing that a possible intestinal intoxication was present, resulted in a loss of twenty-five pounds with no improvement in the asthma. For the past six years he has been having three to four headaches weekly which were not relieved by glasses. The history was otherwise negative. Skin tests were performed with over a hundred proteins. The only clue to a possible etiology was a plus-minus reaction to Staphylococcus pyogenes aureus, presenting a wheal three mm. with a faint erythema of one cm. After the fifth injection of a stock Staphylococcus aureus vaccine he began to improve. An accidental increase of a hundred million bacteria administered on December 22, 1919, was followed by severe asthmatic attacks, the patient commenting that they were "worse than ever" and that "it came out of a clear sky." After February, 1920, he was free from headaches and bronchial spasms and was discharged four months later, still free from asthma. He weighed 160 pounds, having gained twenty pounds. After an interval of relief for almost two years, he returned January 8, 1922, complaining that for a month he had slight occasional wheezing. Skin tests to all proteins revealed only delayed reactions of one plus to Staphylococcus aureus and a three plus to Streptococcus hemolyticus. An active bronchitis followed by continuous asthma, set in one month later. A repetition of the bacterial protein skin tests showed similar delayed reactions. His asthma was relieved after the fifth injection of a vaccine containing the organisms to which he was sensitive.

DRUGS AS THE CAUSE OF ASTHMA.

Skin sensitization can be demonstrated on sensitive patients to various drugs, such as quinine, powdered ipecac, and opium.

Peshkin (17) reported a case of true anaphylactic bronchial asthma in a pharmacist due to the inhalation of powdered ipecac, engrafted on a recurrent seasonal bronchitis. In the fall of 1919 he complained of much running of the nose, following by an irritating and distressing dry cough and respiratory oppression. Soon after he experienced for the first time a typical bronchial spasm. These symptoms would come on when he was working in a drug store and especially when compounding powders. Skin tests performed with many drugs in powder form commonly employed during the influenza epidemic were negative, except pulvis ipecacuanhae et opii (Dover's powder), which gave positive reactions. Powdered opium, ipecac, and lactose —the constituents of Dover's powder—were then tried, giving positive reaction only to ipecac, reacting to a one to one hundred thousand dilution. Powdered ipecac was administered internally without ill effects referable to the respiratory system. Inhalation, however, resulted in the immediate return of the usual nasal and respiratory symptoms. This case also emphasizes the importance of making careful inquiry into the occupation of asthmatics.

ANIMAL SERUM IN RELATION TO ASTHMA.

In a large series of patients with asthma few positive reactions to horse serum were found.

Peshkin and Rost (18) determined the incidence of sensitization to horse serum in a series of 477 normal children, between two and fifteen years. All cases reacted negatively except for a plus-minus reaction in a boy, aged three and a half years, whose history as to diphtheria was negative and who had never received an injection of any kind of serum. Eighty children of the series gave a history of being injected with diphtheria antitoxin and all reacted negatively. Four were injected twice as they had the disease twice. Thus the administration of diphtheria antitoxin incurs practically no risk of anaphylaxis. Yet we must not relax in our efforts to make search for a possible sensitization in every patient about to be injected. They cite a case of asthma in a boy, aged fourteen, with a plus-minus reaction to horse serum and who was given a prophylactic dose of one c. c. (one thousand units) diphtheria antitoxin (19). Within fifteen minutes he suffered a severe anaphylactic shock with the symptoms referable to the skin, intestines, and bronchial tubes.

OCCUPATION IN RELATION TO ASTHMA.

Occupation may have a direct relationship to the cause of bronchial asthma. Epidermal protein or dust is almost invariably the offender. Occupation frequently explains the development of sensitization after the age of forty. The following occupations are associated with asthma, although the occurrence is not usual; bakers sensitive to wheat proteins; hostlers sensitive to the protein of horse dandruff; furriers sensitive to rabbit and musk rat hair proteins, and jewel polishers to the dust of boxwood and orangewood. Sensitization to the proteins in medicinal herbs may occur in the workers on the fields. Sensitization is more common to ipecac, a perennial shrub growing in Brazil and other South American States.

Wheat protein as a direct cause of asthma in occupation is responsible for the greater number of sensitizations.

PASSIVE HUMAN ANAPHYLAXIS.

It is of interest to note, since Schloss (20) demonstrated passive anaphylaxis in guineapigs injected with the serum of a sensitized patient, that the danger of induced human anaphylaxis is real.

Ramirez (21) draws attention to the practical importance of this possibility in blood transfusion and reports a case of passive anaphylaxis which was apparently induced by the blood of the donor. In the recipient, hitherto free from any evidence of sensitization, there developed an acute attack of bronchial asthma after the transfusion on being brought in contact with horses. The donor readily admitted being subject to a persistent and long standing asthma and bronchitis. When he was tested he was found to react to horse dander more acutely than did the recipient.

Wolfe (22) reports a case from the maternity service of the Long Island College Hospital, in which definite anaphylactic phenomena were manifested after a blood transfusion; in this instance her son was the donor.

ANTIANAPHYLAXIS.

Schloss (23) first called attention to human antianaphylaxis in four infants, three of whom were sensitive to egg and one to milk. Following the occurrence of symptoms, after the ingestion of a certain quantity of egg or milk, the cutaneous reaction disappeared. After a period varying from twenty-seven to forty-five days, cutaneous sensitiveness returned and symptoms of urticaria were caused by the ingestion of the toxic foods.

A case in the private practice of Dr. W. L. Rost is that of J. S., aged five, with a previous history negative to asthma. She was seized for the first time with a violent anaphylactic shock on January 19, 1921, shortly after the ingestion of a pear. Cyanosis due to bronchial spasm was extreme and death seemed certain. Heroic measures, however, were successful in checking the attack. At intervals up to twenty days after the initial shock reaction to pear was still negative. Subsequent mild asthmatic attacks always followed the ingestion of a small portion of pear. It was unfortunate that the period of induced antianaphylaxis could not definitely be determined in this case.

The practical significance of this occurrence is obvious and must be remembered when performing the skin tests.

SENSITIZATION IN THE NORMAL AND ABNORMAL.

The presence of the symptoms in patients with sensitization informs us that their tolerance to the offending protein is broken down. The initial sensitization occurs long before the symptoms of asthma become manifest. The frequency of sensitization can be approximately determined by referring to a normal series.

In a recent paper Peshkin and Rost (18) determined the incidence and significance of sensitization in 502 children between two and fifteen years; 9,406 tests were performed with seventy-four food and epidermal proteins. There were five positive reactions occurring in three children or one half per cent. of the total number of children. Forty-eight children gave sixty-seven doubtful reactions or nine and one half per cent. of the total number of children tested. Thus ten per cent. of the children show positive and doubtful reactions which decreases as the age increases, indicating progressive desensitization. They show that the incidence of sensitization in normal as compared with abnormal children (5) indicate that the ratios are correct. The foods giving positive and doubtful reactions are frequently indulged in and compose an essential part of the dietary of these children. The foods giving the greatest number of reactions in these normal correspond proportionately with those in the abnormal children. It is maintained that all reactions above the control are true protein sensitizations and should be regarded as potential anaphylactic cases. It is necessary to institute prophylactic measures in normal cases presenting sensitization without symptoms. Time alone can answer in how many of these cases showing sensitization symptoms may develop. One case, however, is cited from the normal series which subsequently developed asthma.

O'Keefe (24) has shown that foreign proteins may pass from the mother to child through her breast milk in sufficient amounts to result in sensitization of the infant. Some of the infants were found sensitive to proteins; they had no history of ever having ingested. The mother in no instance showed sensitization to the protein to which her child reacted. One nursling of six weeks gave a positive reaction to codfish. The child's skin cleared up when the fish was omitted from the maternal diet.

We believe that with the accumulative evidence already at hand, it is fairly safe to assume that most cases of hypersensitiveness has its inception during infancy and childhood. Failure to become naturally desensitized during this period emphasizes the reason why, in the course of time, the threshold tolerance to proteins is passed and symptoms develop.

GENERAL CONSIDERATIONS.

In the face of experience we cannot agree with the prevalent trend of opinion that too delicate or fine a reading of the protein reaction impedes the progress of this branch of medicine. No reaction above the control should be regarded lightly. If proved not to be the offending protein, it is well to bear it in mind as possible sources of future trouble. Patients have been cited presenting multiple positive and doubtful reactions that got well when one or all of the latter were seriously considered as etiological factors. The extreme necessity of further study in sensitive cases is shown by Rackermann (7) in a hundred cases in which the existing positive reactions were evidently incompatible with the history. Subsequent study showed that the findings of the food or animal protein sensitizations were of distinct importance and of use in the further treatment in thirteen per cent. of these cases.

No difficulty should be encountered in determining the relation between the offending protein and symptoms in cases presenting one or several sensitizations. If the administration of the protein causes symptoms or the withdrawal results in partial or complete relief the conclusions will be obvious. Patients with many reactions are often difficult to manage from the viewpoint of treatment and determination of the responsible protein. Multiple sensitization is most commonly observed among patients who begin to have asthma during infancy and it is quite frequent among those patients with beginning asthma during the period of childhood. The rapid cessation of symptoms upon the withdrawal of the offending proteins in uncomplicated cases, while simple, are nevertheless impressive and are most frequently demonstrated in children. A complicating secondary bronchitis often require appropriate vaccine treatment to bring about complete relief. Usually the duration of asthma in children really matters very little, in so far as structual lung changes are concerned. If a slight emphysema is present and the asthma relieved, we can expect the lungs to be restored to normal. If asthma continues into the adult period the longer it is present the more pronounced may be the resultant bronchitis and emphysema. The asthmatic habit may take root and the physiobiochemical equilibrium disturbed to such extent that despite the institution of proper treatment against the primary and secondary causes failure of cure results. Positive reactions in patients with organic changes in whom asthma began after the fourth decade require interpretation. These sensitizations have probably been present for many years and against which the patient has acquired a tolerance, asthma being a secondary manifestation to the existing disease. However, cases are met where the conditions are entirely independent and the removal of or treatment against the offending protein (usually epidermal or dust) clears up the asthma.

We believe that if all cases of bronchial asthma in young adults and especially in children were carefully investigated and the results of treatment observed for a long period of time, the number of sufferers from this distressing malady would greatly decrease.

That a goodly number of asthmatic patients have been benefited and relieved since the advent of practical protein vaccination can not be denied. This new branch of study has taken a definite and permanent place in medicine. Further research will remove many difficulties which are encountered at present.

SUMMARY.

The precutaneous or scratch test is the method of choice and is most commonly employed in demonstrating protein sensitivity.

The incidence of protein sensitization in bronchial asthma reported by Walker (6) strikes a representative average.

Food is the most frequent cause of asthma during infancy. With the onset of asthma after the period of childhood, food plays a minor rôle.

Beginning with childhood, epidermal and dust proteins are the most important of which horse hair and dandruff are the most common offenders. In certain localities, however, rabbit hair found in pillows and mattresses is responsible for a greater number of sensitizations.

Postseasonal pollen asthma is not always due to secondary infection. Protein pollen intoxication is the cause in some cases and treatment with pollen extract clears up the asthma.

Bacterial asthma probably constitutes about half of the patients seen. More general interest and investigation should be encouraged in lieu of the present omission of the bacterial proteins in the skin tests.

The marked variations of the reported percentages of sensitization by different observers depends upon the technic and interpretation of the tests, the preparation and number of proteins used, the locality, environment, occupation, age and nationality of the patient along with the age of onset of asthma.

Occupation may have a direct relationship to the cause of asthma.

The incidence of sensitization in normal as compared with abnormal children indicates that the ratios are correct.

Skin tests against horse serum must be performed in every case of bronchial asthma before the administration of therapeutic sera in spite of the fact that it practically incurs no risk of anaphylaxis.

Antianaphylaxis can be clinically demonstrated in some cases of asthma. The practical importance of this occurrence must be remembered when performing the skin tests.

Human induced passive anaphylaxis is a clinical fact.

To fix the responsibility in paroxysmal dyspnea requires a complete series of cutaneous tests accurately performed and properly interpreted together with a thorough history and physical examination.

I take great pleasure in acknowledging my grateful appreciation to Dr. W. L. Rost, chief of the Children's Clinic of the Mt. Sinai Hospital, who has generously permitted me to utilize the material at his clinic for the study of the many observations and conclusions reported in this paper.

Fractional Test Meal Method of Rehfuss Versus Single Test Meal of Ewald

By M. GOLOB. M.D.,
New York.

Assistant in Gastrointestinal Diseases, Vanderbilt Clinic, Columbia University, and Department of Gastrointestinal Diseases, the Bronx Hospital.

In its proceedings for conducting a test meal analysis of the stomacn contents, the medical profession is largely divided between the fractional method of Rehfuss and the single test meal of Ewald. And in order to reveal more clearly the merits and demerits of these respective methods, a detailed description will be given of each, together with a brief survey of the salient points in the analysis of gastric chemistry.

The Ewald test breakfast consists of the administration to the patient on an empty stomach of thirty-five grams of white bread or four soda biscuits, and 240 c. c. of weak tea or water, the contents aspirated forty-five minutes after the beginning of the meal. At the completion of the aspiration one or two bulbfuls of air are injected into the stomach to smooth out the rugæ before gentle suction is employed. After a portion of the contents is aspirated the funnel is again connected, two hundred c. c. of water are thoroughly mixed with what remains in the stomach, and the combined contents withdrawn, thus permitting the determination of the total quantity of the contents for physical, chemical, and microscopic study.

The fractional method was first brought to the attention of the medical profession in 1914 when Rehfuss introduced the use of the small tube for a continuous study of the gastric secretion, after a test breakfast conducted over a period of two and a half hours at fifteen minute intervals. The object in removing only a little with each aspiration (say five to ten c. c. of gastric contents) is to avoid that interference with the stimulation of the gastric secretion by the test meal, which is consequent upon larger extractions. Each specimen is titrated with a decinormal solution of sodium hydrate for free hydrochloric acid and total acidity. At the end of the digestive phase of two hours, a test for starch is made with iodine, and if negative indicates that complete emptying of the stomach has taken place; so that further attempts to aspirate would bring up but two or three c. c. of mucus and saliva. If, however, the secretion of the stomach continues, we know that we are bordering on a pathological soil. Crohn and Reiss (1) assert with emphasis that "in the hundreds of cases observed with a functionally normal digestive organ, the stomach empties itself promptly at two hours, and thereafter no further secretion is obtainable. All cases varying from this standard by showing digestive or postdigestive hypersecretion are regarded as suffering from a functional aberration from the normal secretory standard of health."

As to the relative merits of oatmeal gruel and white bread for the purpose of a test meal, it may be pointed out that oatmeal gruel can be administered without removing the tube and that its freedom from lactic acid renders it not unavailable for the lactic acid test; while the use of white bread with the tube removed, permits of the regular stimuli of taste and chewing, thus keeping the secretion as nearly normal as possible.

Of the many tubes on the market I prefer the Rehfuss tube. Its weighted tip makes its descent more easy, and the spaciousness of its slots, equal in aggregate diameter to that of the tube, renders it peculiarly adaptable to the aspiration of a composite sample of the gastric juice, inclusive of mucus and food debris.

The limitations of the Ewald method are apparent. The total quantity of the stomach contents can be determined by the Ewald method only after a definite amount of water has been introduced into the stomach. As the patient has already been subjected to the inconvenience of one aspiration he is generally spared further annoyance and the operator foregoes this part of the procedure, content with having secured a few c. c. of gastric juice for analysis. To continue further the study of the motor function of the stomach, it is necessary to conduct a duration test. This is done by introducing the tube into the stomach three and a half hours after the patient has partaken of a meal consisting of two soft boiled eggs, seventy grams of bread with butter, and a glass of water. The contents of a fasting stomach must then be studied for the purpose of ascertaining if there is continuous secretion or food retardation. And only by the combination of the tests described can the Ewald method secure information as to the motor function of the stomach.

In the fractional method of Rehfuss, both secretion and motor functions of the stomach are ascertained in the one test and at one seance. The test meal is known to leave the normal stomach in from two to two and a half hours; more or less time would signify impaired motility, hypermotility, and hypomotility, respectively.

We know that the hydrochloric acid in the gastric juice during the early phase of digestion manifests an affinity for proteid and basic substances and readily combines with them, as may be detected by titration with a decinormal sodium hydrate solution, and the use of sodium alizarin as an indicator. It is the acid over and above that required for entering into combination with the substances mentioned that concerns us most; namely, the free hydrochloric acid, the medium in which the cell lining the gastric mucosa finds its normal habitat. It is this acid which carries on a normal reflex of pyloric opening, dissociates vegetable cells from one another, and acts as an antiseptic agent in rendering the gastric mucosa free from invading pathogenic microorganisms, besides seeking the union of the proteid and basic substances. And what most engages the attention is, that because this acid appears in the stomach contents after the saturation of all substances which it binds, it may be negative or very low when tested for in the early part of digestion; so that no inference is warranted regarding the deviation from the normal course of a gastric curve unless it is based on a study made from contents aspirated at the height of gastric digestion. Of course, cases may be met where the binding between the secreted hydrochloric acid and the basic and proteid substances is so slight in the early period of digestion, that a test at that time will show the acid in large amount.

In performing gastric analysis information is sought from the viewpoint of both etiology and stomach function. The one is furnished by histopathological, chemical, or bacterial evidence of disease; the other by ascertaining the normal stomach activity regarding its secretory and motor powers—perhaps, as Rehfuss pointed out, the detection of "a normal secretory variation without tangible evidence of pathology." The patient's state of mind is an important factor in the determination of the stomach contents. General apprehension and fear of suffocation on first swallowing the tube may so depress the secretory function of the stomach as to render unreliable any test conducted at the time. It is for this reason that the Ewald method is often so erroneous. The fractional method, with its testing period spread over a longer interval of time, takes little cognizance of this momentary depression of gastric secretion, affords the patient time for his uneasiness to wear off, and thus obtains an acid curve more nearly normal.

Another point requiring emphasis is that not all stomachs have the same emptying time, an orthotonic stomach being able to empty its contents in much less time than an atonic stomach. It is therefore reasonable to assume that this physical difference carries with it also a functional disparity in the secretory activity, and that only by the fractional method can this be detected.

That the secretory output of the stomach can be studied to better advantage by the fractional method is attested by Mohler and Funk (2) who, in their study to investigate the gastric function in early and in advanced cases of tuberculosis, point out the lack of harmony in the reports of various workers, and emphasize the value of fractional estimation because of the possibility of establishing a "secretory curve" as an aid in determining the gastric functions. By this method these writers found in one case a type of a curve representing psychic achylia in which the total acidity ranged from two at fifteen minutes, to five at the end of one hour, with a total absence of free hydrochloric acid and apepsia. Following this period the total and free acidities rapidly rose to forty and thirty-two respectively. This type, if studied by the older methods of gastric analysis, would be interpreted as a case of true achylia gastrica, rather than the pseudoachylia it is known to be.

Douglas Vanderhoof (3) began to employ this method of gastric analysis in 1915, and has since adopted it as a routine procedure. In conclusion he stated that he has been distinctly impressed with the increased information obtained by the fractional test meal examination. Anderson and De Albora (4) in a study of stomach contents in 150 patients, have charted their findings in the normal type, achylia gastrica, reflex type, duodenal ulcer, and gastric ulcer. These authors have stated in their conclusions that the fractional estimation of the gastric contents is "sufficiently practicable" to use as a routine procedure in gastrointestinal disease, notably in duodenal ulcer, achylia gastrica and reflex gastric conditions. It furnishes valuable aid in making a diagnosis, and may often obviate the necessity for a röntgenological study.

Cheney (5) asserts that because of better methods for investigation of gastric contents more information is obtained now than a few years ago. He voices his conviction that the best results are obtained by following the plan described by Rehfuss in his article in *Oxford Medicine,* which includes the examination of the fasting stomach contents as well as of those obtained after the Ewald test meal by half hour extractions. Barker (6), in speaking of the continuous study of the gastric secretion after a test breakfast, remarked that the results are in many instances surprising, and declares it probable that hitherto we have often been deceived as to the secretory activities of the stomach by limiting ourselves to single examinations of stomach contents after the test meal. It is my thought that the varying states of secretion designated by Hemmeter as heterochylia, if studied in the fifteen minute aspirations over the two hour digestive period, would show at one seance a picture of secretory variance beginning with an anacidity, progressing to hypoacidity and terminating finally with a hyperacidity. I do not wish to convey the idea that heterochylia does not exist, but desire to point out that if submitted to a fractional method of study, its ever changing chemical demeanor would be graphically visualized. The beginning of the digestive period would probably be characterized by the transient inhibition of hydrochloric acid concomitant with the aspiration of the test meal; the acid would then gradually ascend the ordinates, as time continued to creep along the abscissa.

Much weight may be given to the conclusion reached by Kopeloff (7), that because gastric curves from the same individual often vary as much from one another as curves of different individuals, single determinations by the Rehfuss method are not sufficient upon which to base valid conclusions, since they do not take into consideration variations within the individual. I agree with these conclusions which may in a measure explain the state of heterochylia referred to above. But here I wish emphatically to state that variance is a salient feature in the Rehfuss method; that excepting in the case of a true achylia, variation is revealed in the construction of a gastric curve, often as already explained, running the full range from achylia to hyperacidity. This feature is conspicuously absent in the single test method. Kopeloff, however, states that a bacteriological study of the stomach, including both the active and resting phases of digestion, is made possible by the fractional method of gastric analysis.

Rehfuss remarks that "while there are some authors, like Bourgot, who consider that the stomach tube has almost no contraindications, there are others who find many conditions which might militate against its use." That there are many who share these misgivings is evident from the numerous methods devised for the study of the gastric secretion without the use of the stomach tube. Leon Minnier's (8) method depends on the principle that catgut dissolves in gastric juice with a rapidity proportionate to the activity of the acid. A pearl of ether is placed in a bag of thin rubber tissue, the sac opening of which is closed with a strand of catgut. The capsule is ingested by the patient during gastric digestion, and on coming in contact with the fluids of the stomach the catgut is dissolved and the capsule bursts. The technic comprises an Ewald test meal and a capsule administered immediately after. The interval between the taking of the capsule and the moment when the patient experiences an eructation of ether, is noted.

When ether eructation takes place before one hour, a diagnosis of hypersecretion is made; between one hour and an hour and a half, normal secretion; after an hour and a half, hyposecretion; no eructation, achlorhydria. The results summarized by this method were as follows:

Diagnosis.	*Interval before bursting.*
Ulcer	Thirty minutes or less.
Hypersecretion	Less than fifty minutes.
Normal secretion	Fifty to sixty minutes.
Hyposecretion	Over sixty minutes.
Cancer	Failure to burst, or bursting after several hours.

The examination is subject entirely to the notice of the patient, which may pass unnoticed. The inconclusiveness of the method is too obvious to need further comment.

Dr. Schlessinger, in 1911, advanced a new method for the determination of the total amount of acid in the stomach by means of the x ray, in such cases of gastric disorders as are unsuitable for the aspiration of stomach contents by the tube. The principle of this test consists in the evolution of carbon dioxide gas arising from the action of a carbonate such as sodium bicarbonate in a stomach that is acid. As a result this will increase the collection of gas in the fundus of the stomach. The procedure requires the ingestion of bismuth cornmeal gruel, and an x ray taken one hour later; after which the patient receives the solution of bicarbonate of soda, and another plate is taken. The marked increase in the space occupied by air as revealed by a comparison of the two pictures forms a basis for the estimation of the acidity of the gastric contents. The following points will be observed, upon instituting this method: Marked discomfort of holding the evolved carbon dioxide, as the patient is requested not to belch. There may be considerable escape of gas through the pylorus, and the small intestine may, as a result, become distended. There may be sudden distention of the stomach, with resulting pressure on the thoracic viscera. Besides exposing the patient to dangers from the x rays, however remote, and involving him in financial expense, the method is cumbersome, and unwieldly for conditions contraindicating the passage of a tube. From the multiplicity of methods devised for the study of the stomach chemistry it may be inferred that none of them are without some limitations; that the methods least objectionable are the two under discussion, and that the one holding distinct superiority is that of Rehfuss.

In going over the literature on this subject, I came across the eleven cases pointed out by Timbal (10) as having been diagnosed as ulcer mainly on the basis of subjective hyperacidity, and in which a test meal analysis (single method) disclosed an absence of free hydrochloric acid and in some cases of combined hydrochloric acid. To this state of achlorhydria, a condition certainly unusual in gastric ulcer, Timbal applied the term paradoxic chemism of gastric ulcer. The author concedes that in certain cases the paradox in the chemism is apparent rather than real, as the height of the hydrochloric acid secretion may be reached long after the hour when the test meal is removed. Admittedly, there are reasons for an absence of hydrochloric acid secretion in the presence of the type of ulcer pointed out by Timbal, namley, the location of an ulcer tending to affect the pneumogastric nerve in a manner conducive to the disappearance of the hydrochloric acid, syphilitic glandular atrophy, chronic inflammation of the gastric mucosa. However, it is reasonable to assume that, if all the eleven cases were studied by the fractional method of estimation, some of them would furnish an illustration of psychic achlorhydria or pseudoachylia one hour after the ingestion of the test meal, only to ascend a plotted curve at the end of one and a half to two hours. The following is a case in point:

Case.—A female, W. R., aged twenty-eight, married, had two children both living and well. Her family history and previous personal history were negative. The patient presented subjective symptoms of gastric hyperacidity, but the physical examination yielded nothing of importance. She was of the mixed habitus, hypersensitive. Pupillary reflexes reacted equally to light and accommodation; knee jerks were equal and active. With a pulse of 60, small pupils, and active salivary glands, it was reasonable to classify her as a vagotonic, and accordingly to expect to find an increased gastric secretion. An analysis of the gastric contents by the single test method on three different occasions gave an absence of hydrochloric acid, and a low total acidity. Thus the subjective or symptom hyperacidity was not substantiated by the objective findings revealed by chemical titration. The patient was placed on a sparing and stimulating diet with large doses of hydrochloric acid, but showed no symptomatic recovery. As she had exhibited marked commotion and struggle in swallowing the tube on each of the three aspirations, I decided to institute in her case the fractional method of estimation. The results obtained are shown in the chart.

Thus, I graphically visualized her stomach acidity: During the first forty-five minutes a psychic or pseudoachylia. As the patient became accustomed to the procedure her apprehension wore off, her spirits grew buoyant, she conversed leisurely with those around her, and the secretory function adjusted itself and gave a plotted curve which portrayed the progress of the gastric secretion over the two hour digestive period. Her treatment was consequently changed to a diet with a rich binding affinity for hydrochloric acid and proper medication, resulting in total arrest of her symptoms. I am here reminded of the emphatic words of Dr. Carman: "No other organ in the human body has been accused of so many disorders which it never had as has the stomach. It has been judged guilty and sentenced to treatment when it was perfectly innocent."

CONCLUSIONS.

1. The fractional estimation of the stomach chemistry by the procedure of Rehfuss is a clinical method of proved value, whereby both motor and secretory activities may be studied during all their phases of digestion.

2. The fortitude and cooperation of the patient can be secured much sooner with the seemingly more elaborate method, than with the single test meal.

3. The single examination is inadequate, and many erroneous interpretations of the secretory activities of the stomach have arisen because of inferences based upon such examination.

4. The ordinary stomach tube does not completely remove the gastric contents. It is objectionable to the patient, causes considerable gagging and swallowing of mucus, cannot be retained in the stomach with any degree of comfort for any length of time, and cannot be left *in situ* until completion of gastric digestion.

5. The single test method of Ewald should more properly be called the single phase method. In contradistinction, the fractional estimation of Rehfuss may be termed the comprehensive method.

6. As aptly put by Best, "the advantages of these curves in its superiority over the older 'one sample test' are comparable to the advantages of the moving picture over a single snapshot."

The Gallbladder Surgically Considered

By HARRY COHEN, M.D.,
New York,
Attending Surgeon, People's Hospital.

The treatment of the infected gallbladder has of recent years been the subject of considerable discussion between the internist and the surgeon. Each has set forth the assertions for his contention and each have shown merit. In this paper the surgical aspects of the disease will be shown preference.

CLASSIFICATION.

Included under the broad heading of gallbladder diseases are cholelithiasis, cholecystitis, pericholecystitis, inflammations of the ducts and vessels, surgical liver complications, and carcinoma. Several surgical conditions are omitted from discussion owing to their relative infrequency. Among these are echinococcus cysts, worms, and amebic abscesses.

ETIOLOGY.

Cholelithiasis is a prevalent condition; gallstones being found in ten per cent. of all adult autopsies and in this large number of cases, ninety-five per cent. give rise to no symptmos. In the remaining five per cent. the symptoms range from a slight to a rapidly fatal peritonitis (1). The enumeration of the etiological factors are omitted here since they are well known or may be found in any textbook.

The most constant symptom is pain in the gallbladder region. The acute colic pains radiating to the back and right shoulder are pathognomonic. Tenderness and rigidity over the gallbladder region are indicative of inflammation which is usually present in five per cent. of the cases and are therefore valuable signs. Fever may be present for the same reason. The socalled intermittent hepatic fever, or Charcot's fever, is present only in severe cholangitis or with a stone in the common duct.

DIAGNOSIS.

The diagnosis of cholelithiasis is of importance. Unfortunately the röntgenogram is not only not of help, but frequently a source of error. With the help at present of the Bucky-Potter diaphragm more cases are being diagnosed. A high estimate for positive findings by the x ray is forty per cent. Much has also been expected of the duodenal tube and bucket as an aid to diagnosis in these cases. A large number of otherwise unrecognized cases have thus been discovered. The use of the duodenal tube and bucket is made in two ways; first by the aspiration of the duodenal contents, with the examination of such contents for bile, blood and pus, and secondly the appearance of the tube under the x ray, especially the presence of marked irregularity in the contour of the duodenum, indicating adhesions. Another means of diagnosis that has been made use of recently to good advantage is the blood chemistry examination, especially the cholesterin content. A high cholesterin content may indicate the presence of stones. From a surgical point of view the most important means of making a diagnosis has been the old fashioned clinical method of palpation. Palpation reveals two things, tenderness and rigidity, both of which may be very mild. An explanation of this lies in the fact of an associated cholecystitis. In those cases where the stones lie dormant and present no or indefinite symptoms, this means of examination will likewise be of little value. A thorough history is important. Symptoms of recurring pain or colic in the right upper quadrant with tenderness and rigidity even though slight in patients with antecedent typhoid fever, or in women following pregnancy or in the proverbial, "fat, fair and forty" establishes the diagnosis of cholecystitis. In these cases the x ray findings help to eliminate a pyloric or kidney condition. Moderate fever or in the severe cases the intermittent fever always means coexisting cholecystitis. Jaundice especially where these clinical findings are present is a positive sign of gallbladder disease.

PATHOLOGY.

Stones may be present in the gallbladder without a cholecystitis; more often a cholecystitis is present. The gallbladder may be slightly thickened or the mucous membrane may be reddened. The gallbladder may be the seat of an inflammation varying in degree from slight to severe without any stones being present.

Case I.—Y. S., aged forty, was admitted to the People's Hospital, April 15, 1917. There were symptoms of acute cholecystitis. At operation acute cholecystitis was found but no stones. Cholecystectomy was done with no return of symptoms.

Stones in the fundus usually produce no symptoms. Stones in the cystic duct are the cause of colic, especially when they attempt to emerge from the duct. The cystic duct may be occluded by stones within or by a growth from without. A single stone occluding the cystic duct frequently is the cause of a gangrenous gallbladder. The inflamed gallbladder may be normal in size, or it may be very large. In one of my patients it extended below the umbilicus. The walls may be very thick or about one inch in thickness. It may also be gangrenous.

Case II.—S. H., aged forty-two, was admitted to the People's Hospital, May 30, 1919. The patient had a fifteen year history of gallstones. The present history, one week's duration of the trouble with acute pain. At operation a very large gangrenous gallbladder with acute pericholecystitis was found. In the enormously dilated cystic duct there were two large stones occluding the lumen.

The contents, besides stones, may be normal bile, turbid bile, mucopus or pus.

Case III.—H. R., aged forty-two, male, was admitted to the People's Hospital, January 1, 1920. There was a history of gallbladder attacks for a year. For one week the pain was severe, with fever, pain, tenderness and rigidity in the gallbladder region. On operation the gallbladder was found gangrenous filled with bile and pus and many stones. The cystic duct distended. Cystectomy with drainage was followed by an uneventful recovery.

In cases of hydrops the secretion is serous or mucoid and contains no bile.

Case IV.—M. W., admitted to the People's Hospital, June 30, 1920. The patient had a six year gallbladder history. At operation a hydrops of the gallbladder was found with the cystic duct firmly occluded by a single stone. The gallbladder was markedly distended; no adhesions. The gallbladder was filled with a thick mucus, there was no bile. A cystectomy was followed by an uneventful recovery.

In cases with several attacks or secondary to a gangrenous gallbladder or hydrops, the gallbladder may shrink up so that when this region is explored at the time of operation, the gallbladder may not be found or may be fibrous.

Case V.—E. D., aged seventeen, admitted to the People's Hospital, June 27, 1919. The patient was operated upon by me one year previously for an acute catarrhal appendicitis. During the past year he had several attacks of cholecystitis. On admission to the hospital the patient suffered with a severe attack which required one week to subside. X ray showed a small solitary stone the size of a pea. At operation the typical small shrunken, shrivelled up gallbladder was found, also a small calcareous round stone occluding the cystic duct. Cystectomy was followed by an uneventful recovery. There has been no recurrence of the symptoms since.

A frequent pathological condition and the cause of many symptoms are gallbladder adhesions uniting the organ to the surrounding viscera especially the duodenum and pylorus.

Case VI.—I. G., aged thirty-seven, male, admitted to the People's Hospital, February 26, 1921. There was a history of gallstone attacks for nine years. During the past week an acute cholecystitis had developed. At operation an acute cholecystitis was found with the bladder full of stones. The bladder was very firmly adherent to all the surrounding viscera including the stomach, duodenum, omentum and abdominal wall. The adhesions were separated, a cystectomy was followed by an uneventful recovery.

Cancer is occasionally primary but most frequently secondary in the gallbladder and ducts. In one of my cases it was secondary to a stomach cancer. Of surgical interest in this condition is the fact that where primary, there is an associated history of gallstones in a hundred per cent. of the cases. The chief symptoms are jaundice and slight pain. The gallbladder is usually distended and palpable which tends to differentiate this condition from obstructive jaundice in which case the gallbladder is small. This is the substance of Courvoisier's Law.

A stone after escaping from the cystic duct may locate itself in any part of the common duct. The two favorite places are the middle of the duct and the ampulla of Vater. In these cases the common duct may enlarge to the thickness of a thumb. A stone in the ampulla may give intermittent symptoms acting in a ball valve way. An infrequent location for stones is in the hepatic ducts or occasionally even in the liver. A gangrenous gallbladder may rupture into the peritoneal cavity.

A suppurative gallbladder may do likewise, but more frequently may rupture and cause a localized abscess between the gallbladder and the liver, or may rupture into the liver and cause a liver abscess. An abscess of this kind is usually large and single. Pylephlebitis or infection of the portal vein is a late complication and almost always fatal. In several cases the diagnosis was confirmed by the examination of the blood count. In these cases the white cell count shows a marked leucopenia in the neighborhood of 4,000, at a time when the temperature may be very high. This condition of leucopenia has not been described to my knowledge, or if it has I have not seen it. The final stage of this condition may be described as multiple abscesses of the liver. These abscesses vary in size from miliary to a very large size and may number in the thousands. In one such case a large septic thrombus was found in the portal vein. In these cases the spleen is usually enlarged.

Nephritis is a frequent complication especially in the severe forms of gallbladder infection. Likewise myocarditis. In several cases of jaundice operated upon by me, I had no difficulty with the control of the bleeding. I have found that hemorrhage in these cases is more feared than encountered. In none of my cases was there an associated diabetes present.

INDICATIONS FOR MEDICAL TREATMENT.

The majority of cases with indefinite symptoms are medical, also where the diagnosis is in doubt, jaundice excepted, and where the attacks of colic are few and far between. Postoperatively every patient should be placed under the care of an internist, since the underlying cause of gallstones still remains and only the end results are relieved by operation.

INDICATIONS FOR SURGICAL INTERVENTION.

The one symptom that causes the patient to seek surgical relief is colic. Next follow constant pain, acute inflammation and obstructive jaundice. In cancer a palliative operation as a cholecystenterostomy or occasionally an excision of a small growth may afford relief. In solitary abscess of the liver, drainage frequently is successful. In pylephlebitis and in multiple liver abscesses, surgical drainage of the gallbladder may afford temporary relief. The prognosis in these cases is grave with or without operation.

POSTOPERATIVE COMPLICATIONS.

As in all operations hemorrhage and shock are to be considered. However, these complications are rarely encountered in uncomplicated cases and in the severer or complicated ones can be avoided with proper precautions. Care in the ligation of the cystic artery will take care of the hemorrhage. Pneumonia is also a complication, but not a frequent one. It developed in one of my patients. Recovery took place in that case. Late complications are recurrent stones, methods for the prevention of which I do not know. This is one of the reasons that these patients should be treated postoperatively by the internist. In one of the cases where I operated on the patient there developed recurrent stones four years after operation. In one patient there developed stones with urgent symptoms sixteen years after an operation. Infection of the wound occasionally results in a wound hernia which can easily be remedied by a subsequent repair operation.

ASSOCIATED PATHOLOGICAL CONDITIONS.

1. *Appendicitis.*—In the majority of gallbladders removed unless a distinct contraindication existed, the appendix was excised. In a large number these appendices were found to be the seat of chronic inflammation with adhesions, narrowing of the lumen and other evidences of pathological changes.

2. *Pyloric ulcer.*—

Case VII.—B. G., aged twenty-eight, admitted to People's Hospital, July 20, 1916. There was a three year's history of ulcer of pylorus and of cholelithiasis. X ray showed an ulcer of the pylorus. Cholecystectomy was done for a bladder full of stones and gastroenterostomy was also done. There was an uneventful recovery and the condition of the patient today is normal.

3. *Epigastric hernia and hemorrhoids.*—

Case VIII.—J. K., aged fifty-two, male, admitted to People's Hospital, October 16, 1916, suffering with cholecystitis with stones, epigastric hernia, and hemorrhoids. Operative procedures were performed for the relief of these, which were followed by an uneventful recovery.

4. *Referred symptoms.*—These occur in two groups; where the symptoms are referred to the appendix and where they are vague and indefinite. Of the former group I performed two cholecystectomies in patients in each of whom appendectomies had been performed within a year. In each the symptoms were unabated until the true diagnosis was made and operative intervention instituted. It is interesting to note that in each of these the x ray helped in the final diagnosis. In the second group one of my patients complained of symptoms referable to the ovarian region.

5. *Cholelithiasis and associated gynecological conditions.*—Fibromyoma of the uterus.

Case IX.—M. C., aged forty, was admitted to People's Hospital, September 12, 1916. She complained of gallstone colic and metrorrhagia. On examination besides gallstones she had a large fibromyoma of the uterus. It was a question from which she suffered more, but after a cholecystectomy for the stones, a hysterectomy was performed at the same time as her condition warranted it. The recovery was uneventful.

6. *Cholelithiasis and pregnancy.*—In several attacks of colic have increased in severity and frequency during pregnancy and have subsided after delivery. There are many explanations for this, the two chief being mechanical and chemical. In only one did the symptoms become so severe that operation had to be performed.

Case X.—B. S., aged thirty-two, admitted to People's Hospital, July 13, 1919, with a history of gallstones for three years. The patient was four and a half months pregnant. The increasing severity of the attacks necessitated the operation of cholecystectomy. The pregnancy was not interfered with. There was an uneventful recovery with subsequent normal full term delivery.

Jaundice.—This symptom may be caused entirely by a medical condition in the liver, however, one should bear in mind that it is just as frequently or perhaps more so an indication of a surgical disease. The surgical causes of jaundice are obstruction of the ducts or duodenum, stricture or pressure from without as tumors. Catarrhal jaundice is the chief disease requiring a differential diagnosis. This usually is present in the young and either presents no symptoms or those of gastroduodenitis. This is a distinctly medical disease. Acute yellow atrophy of the liver is rarely confounded with obstructive jaundice. Jaundice may be so faint as to barely be noticeable or the color may be dark green. The onset may be acute or gradual. In obstructive it is acute, the color being intensified with each attack of pain. The pulse is slow and usually there is no fever. Fever means infection and assumes one of the two types described previously. Chills usually accompany this intermittent fever.

Rupture of the gallbladder.—Fortunately although the seat of acute and frequently severe inflammation, the gallbladder rarely ruptures. Occasionally it does. And then it may rupture into the peritoneal cavity and cause a general peritonitis, or it may rupture into the liver and cause either an abscess between the gallbladder and the liver or a liver abscess. Although neither of these conditions are necessarily always fatal, the prognosis is poor.

Cases of septic cholangitis; septic pylephlebitis; multiple abscesses in the liver; stones in gallbladder and duct may occur.

PROGNOSIS.

The prognosis for the uncomplicated cases of cholecystitis and cholelithiasis is about the same as for uncomplicated appendicitis. The mortality is minimum. The prognosis appears less favorable as preoperative complications develop. But even in these cases the prognosis is excellent. The only conditions in which the prognosis is grave, are in cancer and in liver abscesses. In male patients the pathology seems to be more severe, likewise the morbidity. The prognosis, however, is the same.

CONCLUSIONS.

I feel that gallstones, when the diagnosis is positively established, is a surgical disease, requiring surgical intervention. Subsequent medical care is essential. Cases with indefinite symptoms require medical care. Early diagnosis and early operation may prevent the more severe complication as gangrene, empyeme of gallbladder, rupture with liver abscess and even cancer. In two of the cases of jaundice operated by me a diagnosis of carcinoma had been made, yet neither had a cancer and both made excellent recoveries.

An Aseptic Local Anesthesia as Applied to the Anal Region: With Especial Reference to Anesthetic Composition*

By EDWARD G. MARTIN, M.D.,

Detroit, Michigan,

Proctologist, Detroit Receiving Hospital; Associate Proctologist, Harper Hospital; Associate Professor of Proctology, Detroit College of Medicine and Surgery.

It is my desire to avoid reference to the many technics of securing local anesthesia in the anal area with the exception of stating that they have been criticised for lack of asepsis, for failure in many instances to produce complete anesthesia, for a lack of speed in its production, and for the distortion of the surgical field by distention.

I wish to describe briefly a perfected technic that in my experience has proved its worth, soundness of principle, and superiority over any other local anesthesia technic that I have used, witnessed, or found described in the literature. It has seemed to meet the objections to local anesthesia from every viewpoint.

At New Orleans during the meeting of the American Medical Association in 1920, I described as a part of my essay (1) a local technic, which in principle corresponds to the earlier history of the more perfected method which was developed during the following year, and which has been used in my clinic at Detroit Receiving Hospital during the past year, in over 150 cases, with entire satisfaction.

Following a preliminary hypodermic injection of one sixth grain morphine and one two hundredth grain hyocine hydrobromide, given one hour prior to operation, and repeated at the half hour—the patient assumes a right lateral prone position with the knees flexed and the body rotated sufficiently for convenient exposure of the anal field; following any approved cleansing preparation, an area about one and a half inches posterior to the anus is freshly iodized by the operator himself and nothing is allowed to touch this spot until the anesthesia is complete, except the sterile, two and a half inch, twenty gauge standard hypodermic needle. This needle, attached to any type of syringe, one, two, or three ounce capacity, is plunged through the sterile iodized area where the injection is commenced and continued, pushing the needle on past the anus laterally and superficially, injecting without distending nor distorting the area, a slight elevation ahead of the needle being sufficient; the injection is carried well into the anterior commissure; the needle is then withdrawn, and the procedure is repeated on the opposite side. The skin at the site of puncture will be found elastic enough so that these lateral injections can be carried on past the anus in a straight line, as illustrated photographically. Again, nearly withdrawing the needle, the deep nerve areas in and around the sphincter are thoroughly injected on each side, the needle being carried deeply at two or three angles into both lateral deep areas; the test of insufficient anesthesia being any slight complaint of pain during the later part of the deep injection. From one and a half to four ounces of anesthetic solution with an average of two, have by this time been infiltrated throughout the area, absolutely without distention, and when skillfully injected, has required from one

---

*Read before Annual Meeting of the American Proctological Society, St. Louis, Mo., May 23, 1922.

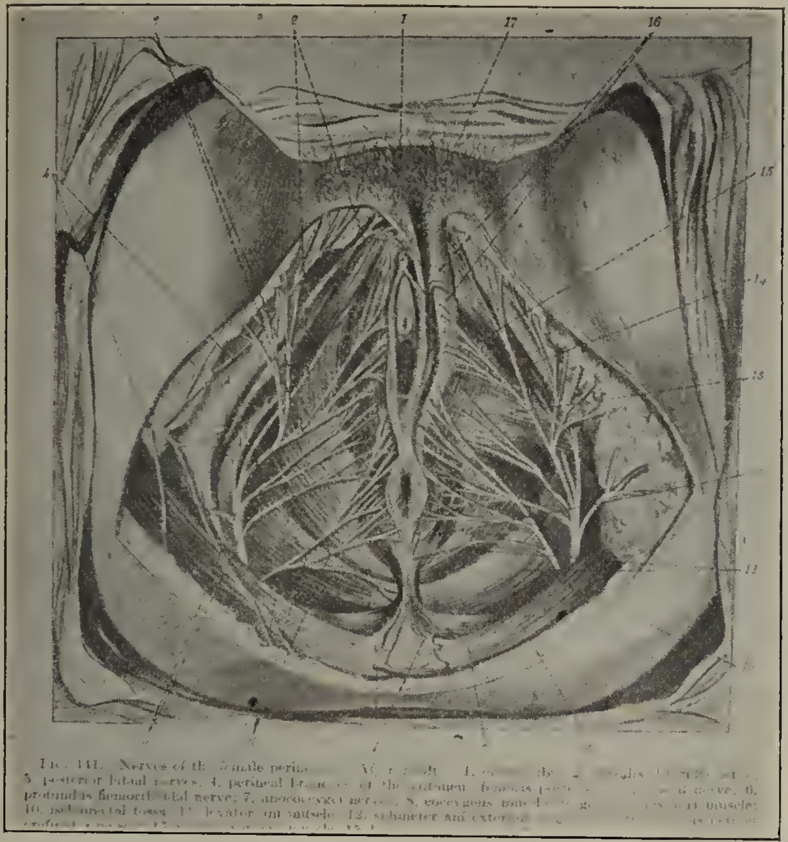

Fig. 1.—Illustrating distribution nerves involved in this anaesthesia.

and a half to two minutes only. The field is now presented for any type of operation desired in the whole anal and perianal area, with anesthesia complete and profound immediately at the end of the two minutes' injection.

The composition of the anesthetic solution is of

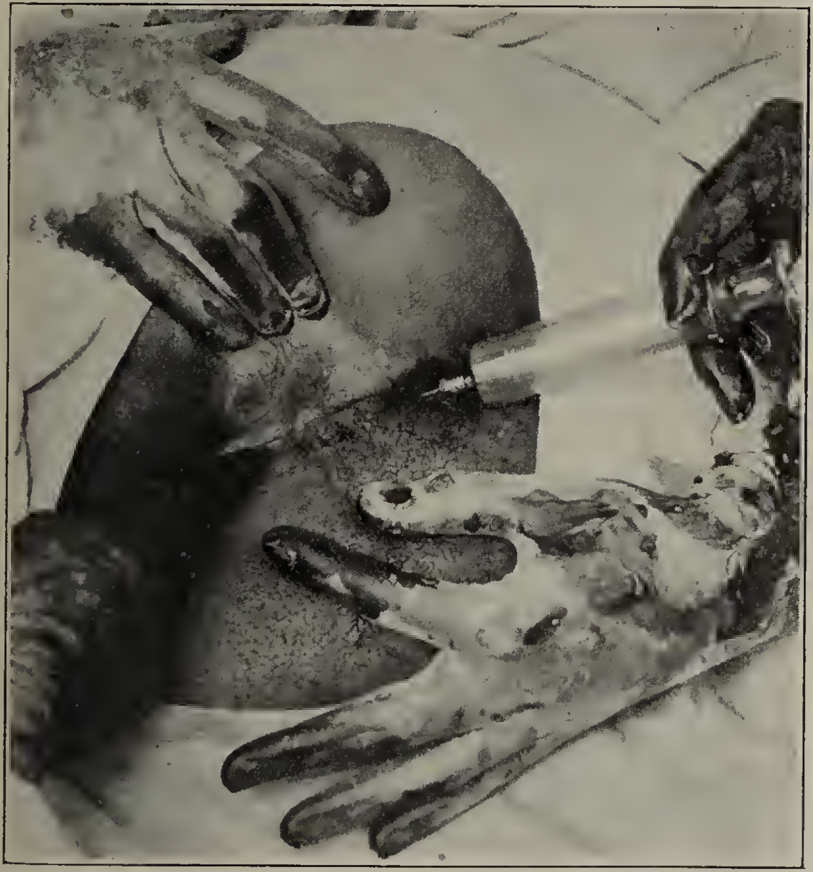

Fig. 2.—Injection having been made through iodized spot, being carried past the anus well into the anterior commisure; finger indicating its progress and length of needle.

interest and importance. Up to 1920 I had tried and discarded several anesthetics, and was using one per cent. procaine (novocaine)—both with and without the addition of adrenalin; this solution was fairly satisfactory, but did not always produce profound anesthesia without distorting the field, and was lacking in the desired rapidity of action; however it proved to be more active when one per cent. adrenalin was added. I tried in short series different combinations, for a time adding mercurochrome as an antiseptic and color agent, but discarded it as ineffectual and unnecessary as an antiseptic.

Years ago it was occasionally the practice to spray the nose with antipyrin solution before applying cocaine; thus suggested, I added antipyrin to the solution, and secured more immediate and pronounced anesthesia. Since then I never have experienced difficulty with the anesthesia lessening during the operation, and am unable to say just how long it does last.

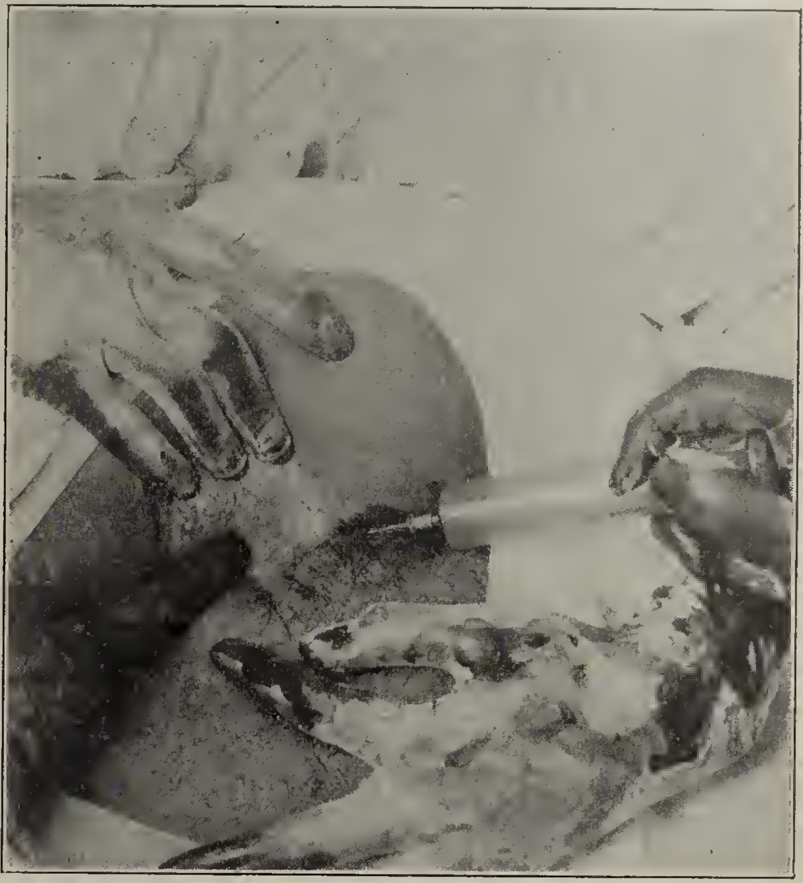

Fig. 3.—Same injection being carried past the anus on opposite side.

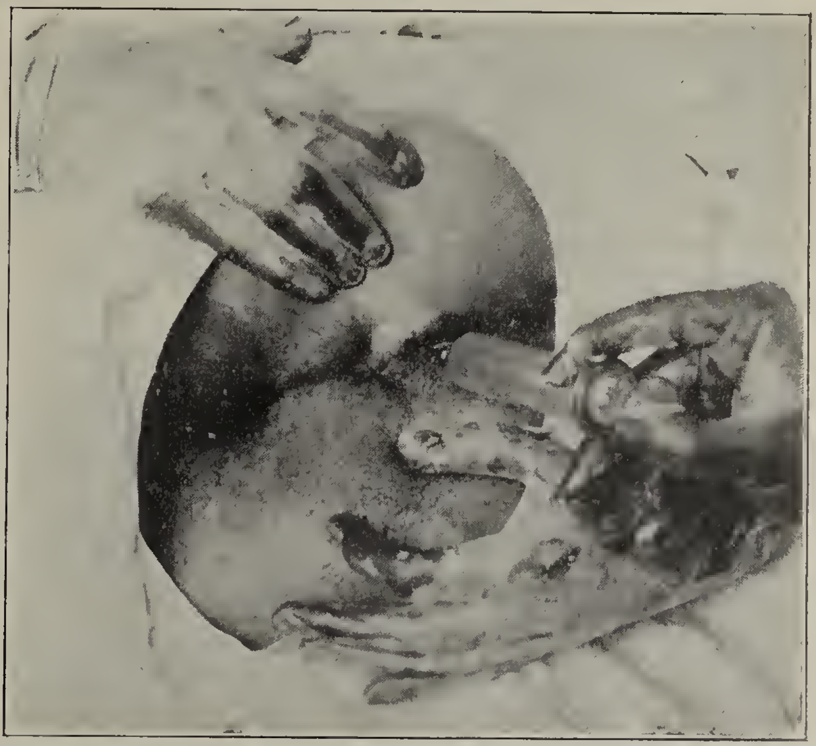

Fig. 4.—Deep injection being made at several angles 2½ inches deep.

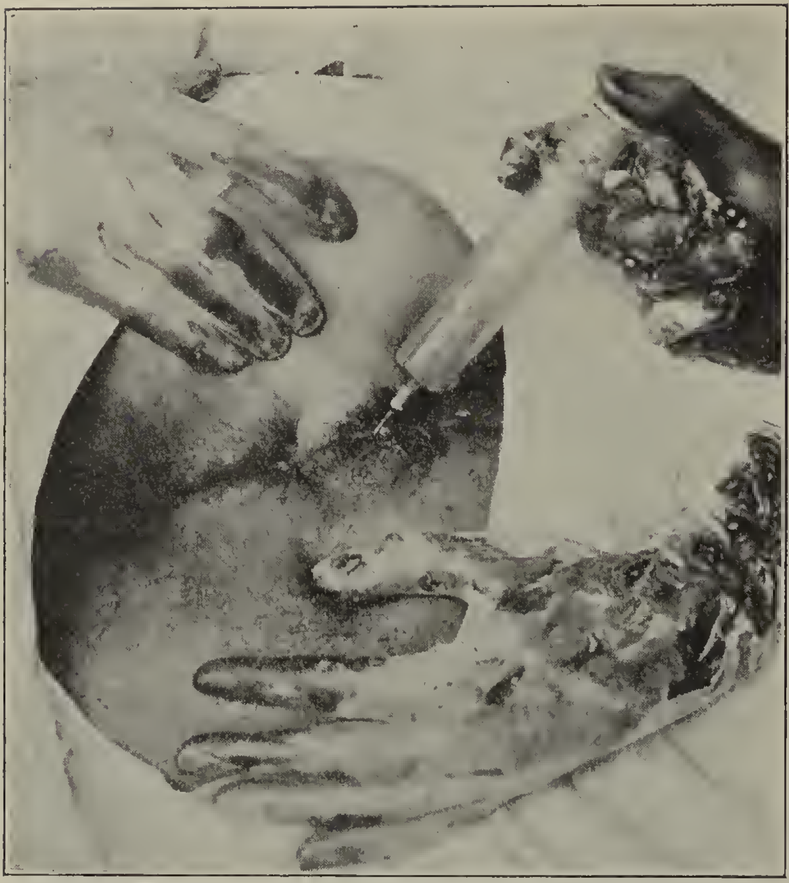

Fig. 5.—Deep injection being carried out on opposite side.

In this series I have used procaine (novocaine), two per cent; adrenalin solution (1 to 1,000), one per cent.; and antipyrin, one per cent. This solution is just tinged with some color medium, such as methylin blue or a red color, to differentiate it from any other prepared solution—(cocaine and procaine have a dangerous similarity of sound). I repeat, in other words: I have been injecting from fifteen to forty grains of procaine (novocaine), ten to twenty grains of antipyrin, and from ten to twenty drops of adrenalin solution (1 to 1,000), in the production of each anesthesia.

It is possible to attain anesthesia following this nerve block, with a weaker solution of procaine (novocaine) if speed and dependability are somewhat sacrificed, but I have found no reason after using two per cent. in this series, for lessening its strength. There is but occasionally confusion on the part of the patient which may last from ten to twenty minutes following injection; this should cause no alarm and requires no treatment.

Two cases exhibited tetanic convulsive movements, lasting about five seconds; there were no other symptoms and no treatment was required; one was an alcoholic, and one a delicate and anemic young woman. No untoward experience, and no toxicities, other than mentioned have been met with.

SUMMARY.

This technic as described offers asepsis, speed, safety, and satisfactory anesthesia, without distorting the surgical field. It offers evidence that procaine (novocaine) is safe when used, even in a great quantities and in stronger solutions than has been the usual custom. It suggests that there has been and still prevails the necessity for constant effort to improve socalled old and tried methods.

Thoracic Abdominal Gate

By JOHN J. RECTENWALD, M.D.,
Pittsburgh, Pa.

The object of the instrument is to make a gate or trapdoor for the pleura, lung, stomach, liver, colon, cecum, ovaries, uterus and bladder. By means of this instrument the thorax and abdomen can be opened and closed at will and treatments may be made over an extended period of time without repeated incisions.

The instrument (Fig. 1) is hinged so that it can be introduced through a rather small opening in the chest or abdomen. It is a small shoulder at the base to prevent the inside door from falling into the cavity. It rests inside the abdominal wall with the tube portion extending out of the abdomen about one and three quarter inches. Its flat base is the internal plate for the chest or abdomen.

The external plate, as shown in Fig. 2, screws down on the outer side of the tubing of Fig. 1, in order to accommodate the different thicknesses of the chest or abdomen.

The internal gate of the instrument (Fig. 3) is made of aluminum, so that radium can be applied while it is in place, or the radium can be placed outside the instrument within the cavity and the cavity closed with a door, as shown in Fig. 3, or Fig. 4. The instrument has a thin arm extending across its diameter, which makes introduction and removal easy. It is made to extend a few millimetres beyond the level of the internal plate, so that there will be less bulging into the lumen of the instrument after removal, thus facilitating the closing of the incision after the instrument is no longer required.

The external gate (Fig. 4) is made to lock with a slight turn into the plate (Fig. 1) and so arranged the slipping of the dressing. Movements of the patient will not open the instrument, and the patient himself is unable to open it. To keep the parts of the instrument which are shown in Fig. 3 in place, gauze is packed into the lumen of the tube.

With this instrument it will be possible to have a good sized opening leading to the pleura, lung and all abdominal organs, allowing for x rays and various forms of light to penetrate into diseased areas, especially for the application of radium and frequent instrumentations. The instrument may be modified by various forms of tubal extensions, to fit the inside plate. The interior of the stomach, cecum and espe-

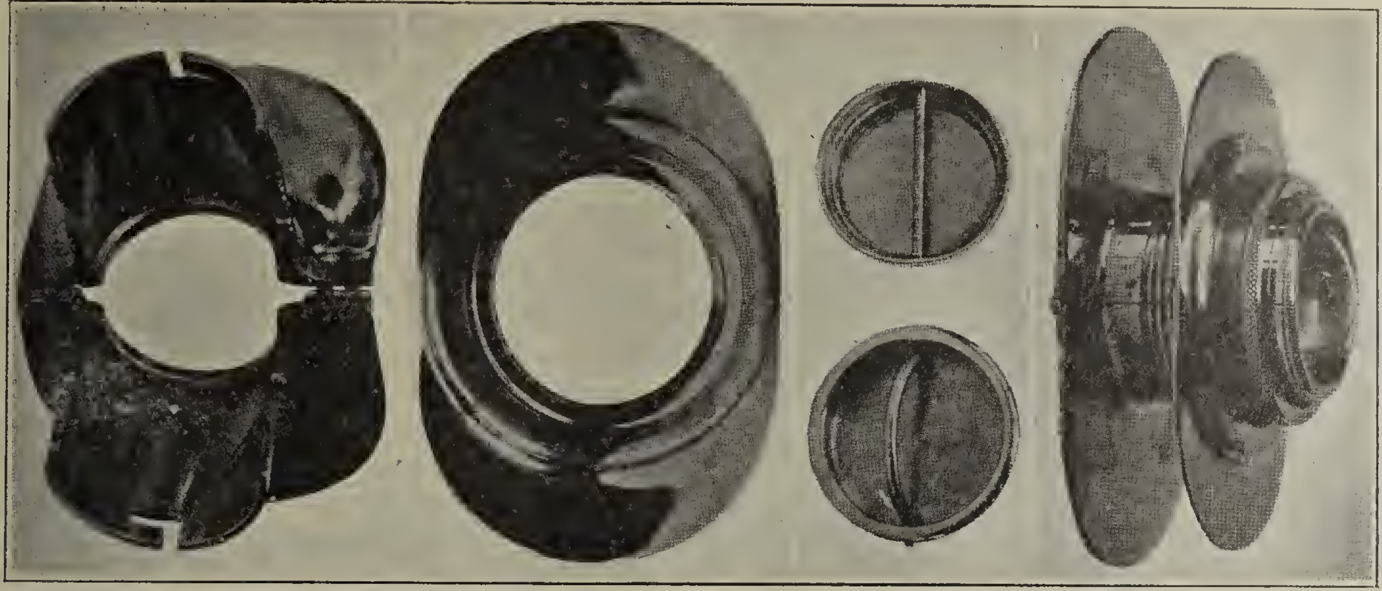

FIG. 1—Various assembled and separate parts of the thoracic abdominal gate.

cially the bladder can be treated at intervals over an extended period of time, the doors being opened and closed at will.

It seems to me that the indications for such an instrument are many. The conception of the instrument was brought about by my desire of applying radium directly to cancer of the stomach in the form of needles, tubes or plates over an extended period of time and avoiding repeated incisions.

139 BROWNSVILLE ROAD.

The Dawn of Surgery

The Ritual Mutilations of Primitive Magic and Circumcision

By JONATHAN WRIGHT, M. D.,
Pleasantville, N. Y.

Wherever we attempt to get back to the beginnings of medicine we find it emerging from under the shield of religion. When man arose to an erect posture, when he came from his cave, he himself took refuge beneath it and with him all sorts of good and evil fled thither, pity, altruism, lust, ambition, all were huddled beneath the panoply which the superstition, the fear, the awe of primitive man before the Great Unknown erected. So if we see surgery creeping out we very naturally look for the marks stamped on it by sacerdotalism and the rituals of magic. They are rather ghastly. Fingers short of their joints, arms stiff with pointing to Heaven, cuts and gashes, scarifications, castrations, circumcisions, things thrust through loops of skin, noses and lips and ears pierced and distorted, we scarcely know thereby whether God is honored or the beauty of woman and the dignity of man are enhanced, so are awe and love and vanity, the cruelty and hate of black magic, the fraud and superchery of man, his selfsacrifice and his selfishness, intertwined as they come out from under their shelter, the shield of the goddess we saw harboring the snakes of the divine Apollo, the sanctuary which shielded criminals and patriots, enemies and friends from pursuers. Religion was the sheet anchor of nascent civilization. Close to this chaos we first find surgery at the beginning of history.

It was not otherwise with prehistoric man. In the depths of his cave where man seldom penetrated, and daylight never, among the magic of his art we see the imprints of the human hand from which one or more fingers or perhaps some of their joints are missing. Archeologists have concluded it is to be accounted for by the supposition that they amputated digits then as a part of the ritual of magic just as they do now, or but lately, among the Australians (1) and the American Indians. Osborn (2) too speaks of it as noted among the traces of prehistoric man, but it has been recorded not only by observers among the North American Indians (3), not only in Australia and America but in another isolated continent, Africa, among the South African bushmen (4), strange, inexplicable furrows traced in the mind of man as he leaves his cave. Teeth are not only broken off or filed for ornamental purposes, but dentistry was carried to astonishing limits, apparently for adornments. Perhaps they had no decaying teeth where they showed, but holes were bored in the sound ones that did show and stopped with gold or shining minerals (5), and this we have not yet traced to magic sources.

With very many of the rituals of magic among primitive men, which have their own affiliation with the birth of surgery, we cannot linger, but it will be interesting, I hope, to spend more time with circumcision and yet a very inadequate space is at my disposal here to tell the whole story of it at the dawn of surgery. It comes to us out of the mists of the past, through the lowest grades of culture, through the high civilizations of the east, but we can only speak of it in Egypt. It was checked by the rise of the Christian hatred of the Jews, but finally came back to us, as this subsided, more or less directly

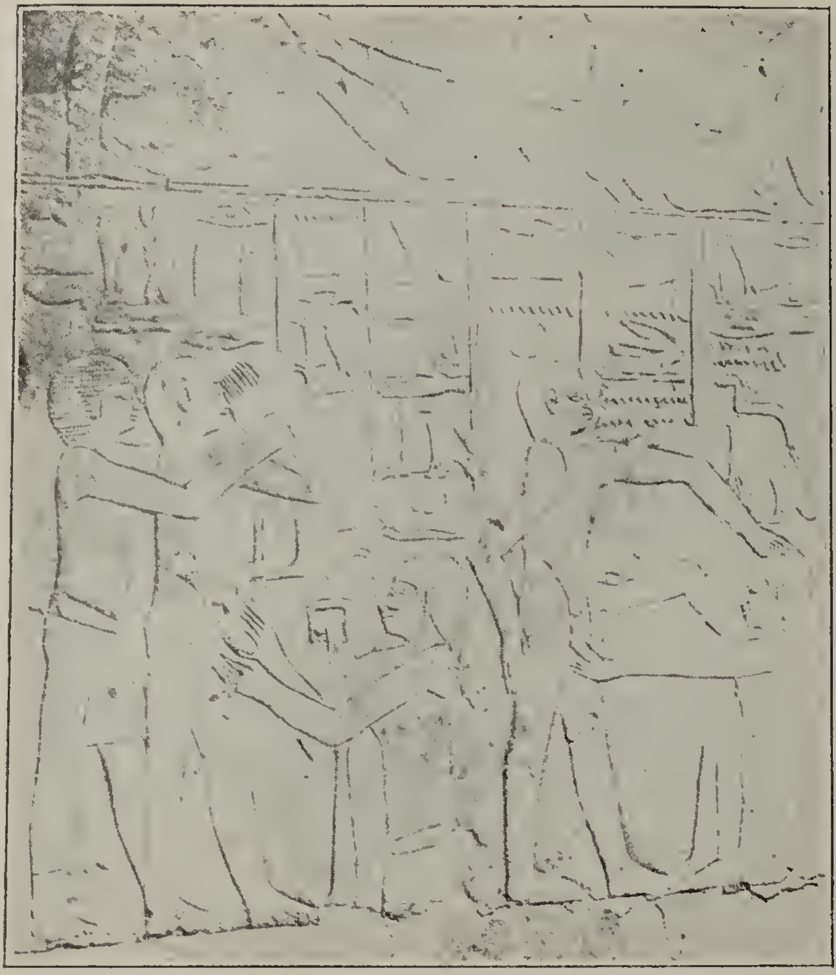

Fig. 1.—From an Egyptian tomb painting at Sapparah of the 6th Dynasty about 3500 B. C. (circumcision).

from the laws of Moses and, to top out the long story, it has reached its climax in our time and has become almost as profitable and a much safer operation than appendectomy and tonsillectomy. But if circumcision had no history while early Christian fanaticism reigned supreme we will find it quite as fruitless to go over the vastly more important epoch in the history of medicine—the era of the Greek civilization. The Greeks turned in disgust from the mutilation of the living body in any form and no race shrank in such horror from the mutilation of the dead. The Hebrews required their priesthood to be physically without spot or blemish, but they, like all Orientals, chopped and hewed the laymen into unrecognizable remnants of living men. The Asiatic Greeks were tolerant of castration and it was a part of the religion of the Syrian goddess, engrafted on their race in hither Asia, but the western Greeks would have none of it.

In a consideration of the surgery of primitive men we plunge at once into our subject and form a valid bond with the interest of the last article on the cutting instruments of the earliest surgery. In almost every Australian tribe studied by Spencer and Gillen there was "a tradition of certain persons who first introduced the stone knife for use in circumcision in place of the firestick, which previously had often caused the deaths of young men at initiation" (6). The use of stone knives in circumcision is noticed in the *Bible* (Ex. V. 25, Joshua V. 2) and it has been very properly inferred (7) that the rite began with the Jews when the tribes were in the stone age and this has persisted in the Jewish ceremony until comparatively recent times. It is widely practised in Africa, especially among the western tribes (8) and "all the Bechuana and Caffre tribes south of the Zambesi practise circumcision" (9). In Brough Smyth's book (10) it is stated that the rite of circumcision is practised among the natives of various parts of Australia, but Ratzel (11) says it is so universal that it is an insult to call a man uncircumcised. Smyth supposed it to have been introduced by the Malays. It is practised in the islands of the south seas in the Pacific (12), but in America it was known to the Aztecs (13) and is still practised by the Caribs of the Orinoco and the Tacunas of the Amazon.

I desire only to go far enough into the literature of this part of the subject to reveal how widespread the custom was and is still among savage tribes in all parts of the world, just as we found the less puzzling custom of prehistoric man as to finger joint amputation, but I desire to make some mention, in connection with the subject, of the remarkable operation of subincision of the urethra which obtains among Australian natives or did obtain when the white men found them and began their extermination. Of what is called the mika operation, Spencer and Gillen say (14): "It is the most extraordinary practice and one which it might be thought would be frequently attended with serious results, but none such apparently ever follow." The operation is performed with a sharp chipped piece of flint or a small knife made of a hand flaked quartzite. The amount of blood lost is at times very large, but nothing is done to stop it and it seems "to cease when the pressure applied by the hand to open out the subincision is removed." Lumholz (15) says a native intimated to him that it was done because they didn't want too many children crying around the camp. However, observation has shown it has little or no effect in this way and apparently it dates back to a time when the natives did not know the reason for impregnation and the nature of the coition of the sexes. Spencer and Gillen (16) say the Arunta tribe have no notion of the origin of the practice and as in this and other tribes the custom is immemorial and applied to all males, there is no foundation for the belief it is a birth control device.

Still it might be commended to the consideration of some of the gentlemen interested in the modern advocacy of the latter. In the tribes in Australia where subincision is practised, the vulva is incised in females so the hymen is divided and Roth thinks perhaps the two rituals have some common origin, but mutilation of the genitals is found under different forms elsewhere. In the Malay Archipelago the clitoris prepuce in females is removed and in East Africa the mons veneris and the labia majora. Among the Israelites of Ethiopia, according to Mérab (18), not only is circumcision performed on male children but on female children as well in the ablation of the clitoris and the labia minora.

Neolithic man in Abyssinia was circumcised according to the testimony recorded on the most ancient of the green slate palettes (19). Herodotus, then, is quite in accord with modern archeological evidence when he says: "The Phoenicians and the Syrians in Palestine acknowledge that they learned the custom of circumcision from the Egyptians . . . but of the Egyptians and Ethiopians, I am unable to say which learned it from the other for it is evidently a very ancient custom" (20). Nor does he venture any hypotheses as to how the remarkable custom arose. The mummified bodies prove that it was general at all periods in Egypt (21). If it had a religious or magical origin, as it probably had, there has been nothing advanced to make it plain what fundamental primitive idea could have been so universal as to initiate its practice in the infancy of the world in such widely separated areas as South America, Asia, Africa, not to mention prehistoric Europe.

Johnston thinks circumcision penetrated into Africa from Egypt, as we know from Herodotus many things probably did, but in view of the testimony referred to as shown in the figures on the slate objects one fails to see how this can be supported, and the inscriptions celebrating the victories of Merenptah (1258 B. C.) of the nineteenth dynasty and describing the slain refer to the Libyans as uncircumcised (22). From the evidence supplied in regard to the Nubians by the desiccated bodies examined at Naga-ed-der there is reason to suppose that in predynastic times it was customary to circumcise the males at the age of puberty. No evidence of a corresponding mutilation of girls, the ablation of the clitoris, was forthcoming though it might have escaped observation. Smith, however, asserts that there was no ablation of the labia minora, a practice not unknown among modern primitive tribes. At Karnak in a little temple devoted to the cult of Chonsu, one of the gods of medicine, there was found a bas relief which represents the operation of circumcision as it was performed in the eighteenth and nineteenth dynasties. The operator with a pointed instrument in his left hand is on his knees excising the prepuce of a child who is standing before him. Behind the child is a woman holding his wrists, and there is another child standing by awaiting his turn and in the background another woman ready to assist (23). The knife was regularly of stone like the one with which Joshua was ordered to circumcise the Israelites in the desert around Sinai, not far from Egypt.

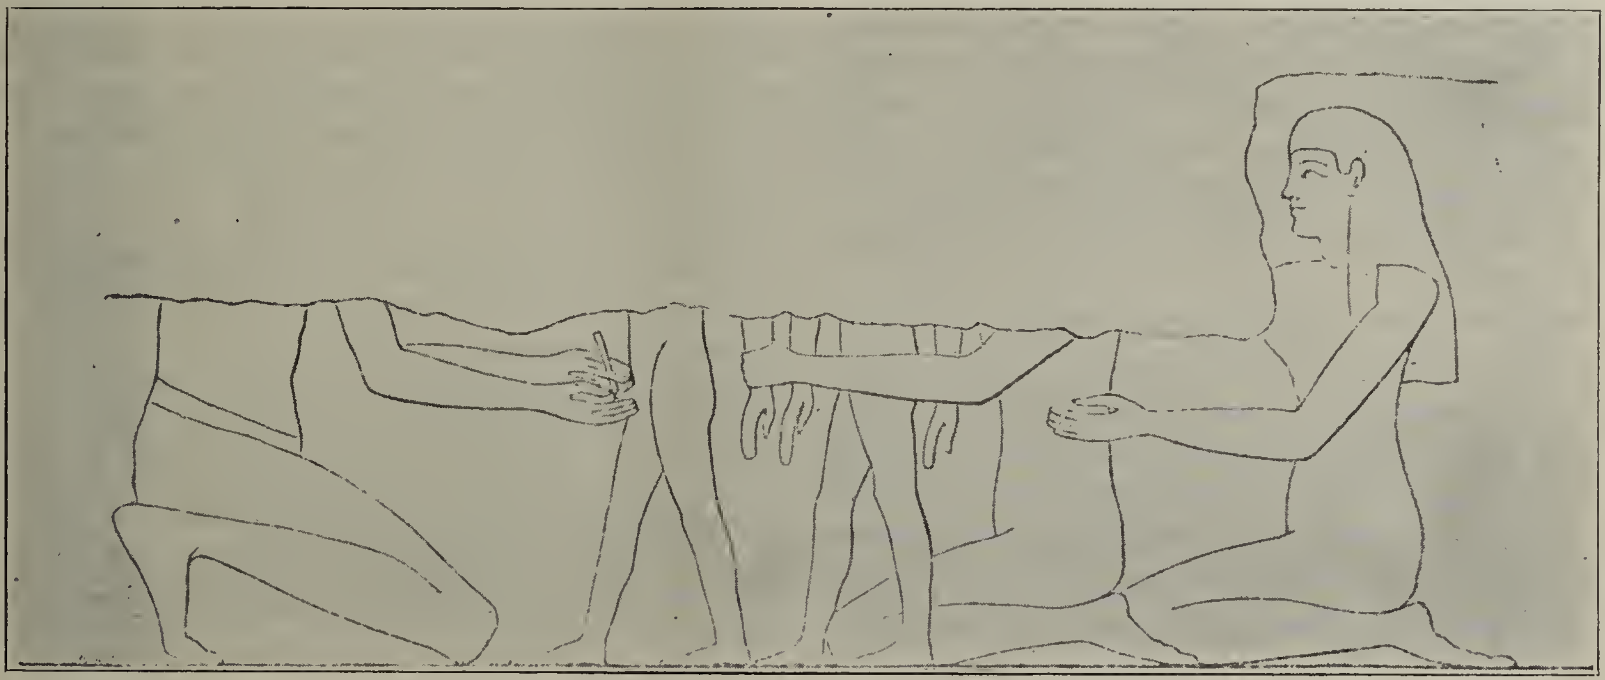

FIG. 2.—An Egyptian operation (circumcision) about 3,000 years ago.

Editorial Articles

JUST LIKE FOLKS

Faults of digestion are the commonest causes of acute diseases and faulty foods the source of most structural defects. In other words, ignorance of food and feeding or wilful ignoring of what we know on the subject is at the bottom of the vast majority of human ills which have a physical origin.

We are so used to these digestive and nutritional disturbances that we take them almost as a matter of course, and consider them as a part of the curse of Adam. Wild animals in the wild are but little subject to disease of such origin, but we look upon these as belonging to a different sphere. The experience of managers of zoological gardens does not bear out this "different-from-them" notion. Studies in the Vienna Institute of Anatomy show that privately kept monkeys, as a rule, died from diseases of the digestive organs, while even the zoo must have its dispensary stocked with bismuth, soda mint tablets, pepsin, etc.

Animals which perforce adopt man's diet, and method of living generally, come to grief, and suffer from the same ills as their illustrious host. This clearly shows that the human animal (which is but a day out of the jungle) is in no way peculiarly prone to nutritive diseases, but is disordered in proportion as his food and feeding are inappropriate. He has simply made a colossal failure along this line. The ignorance of dietetics, by not only the laity but the profession, and the dire results therefrom, is appalling. Within the last month we have heard from the lips of a woman, a college graduate, "I find it is hard to keep babies after you get them. I lost my first one because I did not know how to feed it and I had a fool doctor who could not tell me how," and from another mother, also a college woman, "We know now that our little boy would be alive if we had not given him the wrong kind of food." Experience is a sad and expensive teacher and what doth it profit a woman to have spent four years getting a B. S. and then to have the agony of losing a child because she did not know what and when it should eat?

It is to be hoped that our colleges are beginning to pay some attention to hygiene as well as to Latin and French, ancient history and trigonometry, and that medical schools will some time lay as much stress on dietetics as on pharmacology. A more intimate conception of the facts of evolution needs to be taught, and, in particular, our extremely close relationship in time, as well as in physical character, to our simian friends, for it is all too evident that we can learn much more from them than they from us as to methods of healthy living. We had better begin our studies at once and in earnest. We are finding out how to feed and how not to feed other animals, why not turn the information to further account and apply it to ourselves? The problems are nearly identical and the human being is presumably as valuable as any inhabitant of the barnyard or of the zoo.

SILICOSIS

From time to time the country is shocked by reports of explosions or other disasters in mines entailing a considerable loss of life, but the toll of premature deaths and of years of incapacity produced through the insidious development of anthracosis in this and allied industries is of far more serious moment.

All kinds of inorganic dust are capable of producing fibrosis of the lungs, but silicious dust is by far the most dangerous. Nor is the presence of the tubercle bacillus at all necessary to render such dust injurious. Neither is silicosis a disease that comes on only after years of work in the dust. According to Middleton (*Journal of Industrial Hygiene*, March, 1921), symptoms of silicosis may appear after only six weeks of exposure under bad conditions.

It has been thought that silicious dust was especially injurious to the lungs because of its hardness and the angularity of its particles. Collis has recently put forward a new theory, that silica is injurious on account of its chemical nature—that a foreign substance is harmful in proportion as it is alien to the material of which the body is composed. This theory has been advanced partly for the reason that other kinds of dusts, especially that from coal, is not so injurious to the lung, the collier being relatively free from anthracosis and miner's phthisis. The intravenous injection of a solution of silica into rabbits is said to result in fibrosis of the liver, enlargement of the spleen and changes in the kidney resembling interstitial nephritis but such experiments do not, of course, necessarily prove that silica dust deposited in the lungs produces its effects chemically.

The latest word on the subject is from Mavrogordato, a worker in the South African Institute for Medical Research. He believes that the solubility and chemical activity of diet, e. g., silica, is of great importance; hardness and sharpness are of but little importance. It is not the particle that penetrates the tissues, it is the tissues that take up the particles and intracellular particles are always in phagocytic cells, or in tissues that may be derived from phagocytic cells. In the case of silica dust the cells, after clustering together at various points, remain fixed with their burdens, posibly becoming mummified by silica as eggs are preserved through the action of water glass. "Coal, and the same is true of clay, seems to set up a sort of aseptic catarrh," in which there is a steady exodus of the phagocytes with their ingested particles from the lung.

Three groups of experimental animals were exposed, one to silica alone, a second to a similar amount of silica followed by coal dust, and a third to a similar amount of silica dust preceded by coal. After six months the autopsies showed that in the first group the lungs were grey, in the second they were black, while in the third they were white. Coal dust apparently "sets up a condition in the lung which is inimical to the fixation of silica." Although this is most significant, Mavrogordato does not believe that the protective action of coal dust "is the whole story of the freedom of the collier from miners' phthisis." "It is quite likely that the coal helps them to deal with the small amount of stone dust that they actually inhale, but he believes that better ventilation in coal mines has been the chief factor in the reduction of phthisis."

Some astonishing results in health have been achieved by reducing the dust in metaliferous mines through the application of water and it is believed that conditions will be made still safer by the invention of special ventilating apparatus. In many factories in this country, where men are exposed to large amounts of silicious dust from grinding wheels, the employers are indifferent and the means of prevention of silicosis which might be used are neglected.

BRITISH INSTITUTE OF INDUSTRIAL PSYCHOLOGY.

That the application of psychology to industry has resulted in advantage to the working man has been proved. That it has proved also of benefit to employers is not so generally recognized. That this also is a fact is definitely established in a recent report of the National Institute of Industrial Psychology of Great Britain, wherein it is stated that the Institute has of late received, in the form of subscriptions from manufacturers, sums aggregating nearly ten thousand dollars for the support of its work.

The following outline of the Institute's activities is quoted: 1. The study of the requisites of commercial and industrial occupations, and the development and use of appropriate tests in order to secure, *a,* in cooperation with commerce and industry, a more scientific selection of employees, and, *b,* in cooperation with schools, more dependable vocational guidance for children. 2. The investigation of the most desirable methods for the application of the workers' energies in offices and factories, with particular reference to, *a,* the avoidance of useless motions; *b,* the best arrangement of rest periods; *c,* the decrease of monotony and the arousing of greater interest. 3. The discovery and verification of conditions which make for the well-being of the workers and the most favorable relations between them and the management in regard to pay methods, employees' representation. 4. The study of the various factors which influence the sale of commodities, for instance, designing and advertising. 5. Providing, *a,* lectures for employers and employees, and, *b,* courses of training for foremen, managers, welfare workers and investigators. 6. ALCOHOLIC PSYCHOSES AND PROHIBITION

A statistical study of alcoholic psychoses among admissions to institutions for mental disease during recent years is contributed to the October number of *Mental Hygiene* by Dr. Horatio M. Pollock, Statistician of the New York State Hospital Commission. Some of the significant facts revealed by this study are here summarized.

In 1910, cases of alcoholic psychosis amounted to 10.1 per cent. of all patients with mental disease admitted to institutions. The annual rate of admission of alcoholic cases was 6.7 per 100,000 of the general population. Patients with this form of mental disease constituted 12.4 per cent. of admissions from urban districts, and 6.4 per cent. from rural districts. The rate per 100,000 of population in urban communities was 10.7 and in rural, 2.6. Of the male admissions to hospitals for mental disease in this same year, 15.3 per cent. had alcoholic psychoses; of the female admissions, 3.4 per cent. The rates per 100,000 population were 11.0 and 2.0 respectively.

A marked decline in alcoholic first admissions took place in 1914, increasing in 1915. In 1917 there was a decided reaction, alcoholic cases in that year exceeding those in 1913. Throughout 1918, 1919 and 1920, the number of these cases decreased rapidly, reaching its lowest figure in 1920. In 1921 male cases increased again, but female cases continued to decrease. It was found that the rate of first admissions suffering from alcoholic psychoses is closely correlated with the per capita consumption of liquors. This conclusion is demonstrated by a comparison of the index numbers computed from official reports for the years 1909 to 1920. These figures for New York State are paralleled by data from the State records of Massachusetts. A table giving figures as to the intemperate use of alcohol among first admissions to the New York civil state hospitals during the period 1909-1921 inclusive shows a gradual decline in the excessive use of alcohol, which "constitutes good evidence that a marked change in the habits of the general population with respect to the use of alcohol had been taking place for several years prior to the enactment of the Volstead Law. The change began before the World War, but was halted by the reaction of 1917. Later it was accelerated by wartime restrictions." Tables compiled by the Statistical Department of the National Committee for Mental Hygiene giving the latest available data on this subject are quoted. Among other significant facts, these data show that only 3.1 per cent of first admissions to state hospitals in 1921 were cases of alcoholic psychoses, indicating, when compared with figures from the Federal Census of 1910, a marked general decline in alcoholic insanity. It is shown also that the rate of admissions with alcoholic psychoses in the State tabulated was only 1.9 per 100,000 population, as compared with 6.7 for the whole country in 1910. During 1920, the first year under prohibition, there were fewer alcoholic admissions to state hospitals than in 1921. This reaction, it is stated may be due to lax enforcement of liquor laws, or partly to economic depression.

An interesting excerpt is made from the report of Miss Cora Frances Stoddard entitled, Wet and Dry Years in a Decade of Massachusetts Public Records. Miss Stoddard writes: "The women have apparently gained more than the men under prohibition, perhaps because they are less exposed to the bootleggers' blandishments, and are less likely to seek out the tribe. At all events, the average number of women in all penal institutions of Massachusetts on September 30, 1920 and 1921, the two dry years, was the lowest of the decade, sixty per cent. smaller than the wet years' average, while the total prison population on this date had dropped fifty-two per cent. A decrease of practically one half in the number of commitments to the State Reformatory for Women in the two prohibition years carries a stage farther the story, not only of the passing of alcoholic women from penal institutions, but also of other women offenders."

Another significant fact brought out by Doctor Pollock's study is that alcoholic psychoses have been much more prevalent in urban than in rural districts. In 1910 admissions from urban districts constituted 77.8 per cent of all the alcoholic admissions in the United States, and, since that year, the proportion has increased. A study of first admissions to the New York civil state hospitals from July 1, 1915, to June 30, 1920, showed that 90.9 per cent. of the alcoholic first admissions were from urban districts. The average annual rate was 3.7 for urban districts, and 1.6 for rural districts per 100,000 population. A study of several states from 1919-1921 shows that in 1921 the urban proportion was 84.4 per cent, as compared with 83.9 in 1920 and 85.6 in 1919; and the rural proportion in 1921 was 15.6 per cent. as compared with 16.1 in 1920 and 14.4 in 1919.

Doctor Pollack's conclusions are as follows: "1, Marked reduction in the prevalence of alcoholic psychoses throughout the United States has taken place since 1910. This is due partly to restrictions on the liquor traffic, and partly to changes in the habits of the people; 2, The lowest rate of first admissions with alcoholic psychoses occurred in 1920; a reaction occurred in 1921; 3, The rate of alcoholic first admissions is closely correlated with the per capita consumption of liquors; 4, The reduction in the of alcoholic psychoses has been relatively greater among women than among men; 5, Admissions with alcoholic psychoses come principally from urban districts."

WORKING TOWARD POSITIVE HEALTH

"Health is something positive, progressive, dynamic. It is not merely a vague and negative state of being which remains after active illness has subsided. It stabilizes and enriches life, and no effort is too great that helps to win it. This is the positive ideal of health which the Women's Foundation for Health undertakes to teach." Such a proclamation introduces the foreword of a valuable set of six pamphlets, entitled the *Positive Health Series*, prepared and issued by the above foundation in cooperation with the Council of Health and Public Instruction of the American Medical Association, and the Bureau of Social Education of the National Board of the Young Women's Christian Association.

The Women's Foundation for Health is an incorporated organization whose aim is to correlate the health activities of fifteen national women's organizations into a program of positive health. This set of pamphlets is the response to a demand for a common text to be used and distributed by the foundation. The aim is to bring to the individual woman the conviction that a state of health is only normal, and able to be attained. "The program of health education strives, first of all, to persuade her to assume a personal responsibility for achieving her own physical best. The great public health movement of our day needs to be supplemented by this type of education which calls upon the individual to awake and take her own part—because no one else conceivably can take it. While recognizing society's responsibility for securing sanitary and economic conditions favorable to individual well being, the foundation regards the attainment of health in the last analysis as a matter of personal and social obligation; there is an overwhelming tendency today to consider environment as the dominant force in life, but the individual who acquiesces too far in such a point of view does so at her own moral and physical cost. The false satisfaction that comes from blaming circumstances is a poor substitute for the genuine satisfaction which arises from realizing health. It is always possible to add health to one's life—there are always latent stores at hand for progressive health building. The open sesame to these stores is the sincere resolution of the individual to be a better, finer, more efficient being than she momentarily is."

Although we may be inclined to consider as rather extreme, certainly for some cases, these two last dictums, nevertheless the general attitude and work as a whole of the foundation and its cooperating associations are praiseworthy and give promise of beneficial results. Emphasis is placed upon the periodical health inventory as the basis of progressive health building, but this examination must be more than a merely informative survey; it must be dynamic; it must not only equip the individual with full knowledge of herself and her resources, but must also test her will to health by charging her to carry on.

UNITED HOSPITAL FUND REPORT

Noteworthy gains in efficiency, in scope of work, in numbers treated, and in reduction of cost of treatment are recorded in the recently issued annual report of the United Hospital Fund, comprising fifty-eight nonmunicipal institutions. According to this report, patients are now able to leave the hospitals five days earlier than would have been possible under similar conditions ten years ago. This means a twenty-five per cent. increase in the capacity of the hospitals, and a twenty-five per cent. reduction in the expense of treating each patient. The shortening of the length of time required for treatment has been a steady one and has amounted to about a half day a year. Probably the chief cause of this drop is the marked improvement in facilities for diagnosis and treatment. Other causes are the more frequent consultations of the staff, leading to a better understanding of the individual cases; improved convalescent care, making an earlier discharge safe for the patient; better dispensaries and closer cooperation with them, making it possible for patients to become, with equally beneficial results, ambulatory cases in dispensaries, and so vacate the hospital beds, and development of the work of the social service department, with great advantage to both patient and physician.

The proportion of private patients in these hospitals is less than one fourth. "Few realize," says the report, "what a large contribution is made to the hospitals by their medical and surgical staffs. It is only from private patients that the doctors are allowed to accept a fee. . . . This means that the doctors and surgeons treat seventy-six of every hundred patients without charge."

One of the chief features of the past year was the establishment of the Hospital Information Bureau at the suggestion of the Public Health Committee of the Academy of Medicine. It has supplied to hospital officials information about practices, procedures and costs, has studied administrative efficiency in various institutitions, and has amassed a large amount of data valuable to all connected with or interested in hospital work.

The report strongly endorses the work of Doctor Copeland as Health Commissioner, and quotes him as follows: "Were it not for the beds in the privately endowed institutions of this city, our condition would be beyond words. As I view it, there is every reason why these hospitals must be supported so abundantly that they can provide the expensive instruments, the mechanical appliances, the laboratories, the libraries, and all the accessories to modern and proper medical care. I know I speak for the Mayor and for his associates in the Administration when I say that the city itself is back of the movement to assist the United Hospital Fund."

SPHYGMOMANOMETERS.

Accurate work can be done, even by careful workers, only with accurate instruments. This applies to the taking of blood pressures as to other procedures, for sphygmomanometers have their failings, especially the later and more complicated instruments. By actual test, some machines of the ancroid type have been found to vary as much as six millimeters from a correct reading when the instrument was new, and some instruments, after prolonged service and especially after abuse by being used as tack hammers, have shown wider deviations from the truth. With clean mercury and clean glass, the old U shaped mercury machine was correct to within a millimeter or two, but the new mercury machines which do away largely with the fluctuations of the metal, unless carefully made and calibrated, may not be accurate. Fortunately, a variation of a few millimeters either way from the correct pressure is of little moment in ordinary physical tests, though, in life insurance examinations, it may be of considerable importance to the examined. If one wishes to do accurate work, he should have his sphygmomanometer tested and certified and retested at intervals.

HOSPITAL FIRE LOSSES

The National Board of Fire Underwriters report that, during the years 1919 and 1920, fires to the number of 870 occurred in buildings classified as hospitals, asylums and sanatoriums, an average of more than one fire a day throughout the two years. The Board estimates that the hospital property destroyed by these fires amounted to $1,738,954. The opinion is expressed that it is probably no exaggeration to say that ten times this loss in any other occupancy would scarcely have as serious possibilities in endangering life.

The records show that hospital insurance was rarely adequate in these cases, and the deficits had to be made up, in the case of state and city institutions, by the taxpayers, and through appeals to charity in the case of private institutions. It is the opinion of the Board that, estimating that approximately 10,000 hospitals and institutions in this country accommodate, year in and year out, about a million people, the amount of money wasted in replacing such buildings would be sufficient to put a number of institutions now suffering from insufficient endowment firmly on their feet.

Although a five year period is the minimum of time allowed by the underwriters in determining the socalled characteristic hazard, hence a two-year period is hardly long enough for a definite conclusion as to the most frequent cause of such fires, yet the report discloses the fact that the greatest amount of damage from any single cause of the twenty-two listed was sparks on roofs.

The board recommends the use of all hospital buildings of noninflammable shingles or metal roofing, and frequent inspection by expert fire prevention engineers of all chimneys, flues, stoves, furnaces and electrical systems and apparatus. For institutions located in rural districts, even more stringent protective measures are necessary. "The importance of the design and the location of exits cannot be over-emphasized," says the report. "So far as is practicable, only exits of the horizontal type should be provided. In designing exits for hospital purposes, consideration must be given to the possibility of removing helpless patients under fire conditions; horizontal exits leading to outside covered ramps, having grades such as to permit the wheeling or carrying of patients, provide maximum safety for helpless inmates housed above the first story. Such ramps should be wide enough to afford simultaneous egress and ingress. While large floor areas are conducive to economic operation of hospitals, it should be realized that they greatly increase the fire hazard. In general, areas should be restricted as far as is consistent with economic operation, and cut off by standard parapetted firewalls having all openings protected in the approved manner." The report closes with recommendations for strict enforcement of rules prohibiting smoking and the careless or overabundant storage of volatile liquids used in hospital work. Electrical apparatus should receive its current from a circuit distinct from the regular service lines. Provision should be made for adequate and carefully supervised fire prevention apparatus and equipment, and alarm systems and fire drills should be inaugurated.

MUNICIPAL HEALTH CENTRES.

So many of the larger cities of the country are about to establish health centres, or have already done so, that an article on this subject in a recent issue of the *Monthly Bulletin* of the Health Department of Boston is of timely interest. Among cities, other than New York, possessing health units, Philadelphia and St. Louis head the list as having the largest number—ten. In Philadelphia experiments are to be inaugurated in city owned property, and centres have already been established in three story, rented buildings in congested districts and on business streets. St. Louis has ten buildings, leased and equipped by the city. Cleveland and Buffalo come next with seven centres each. Buffalo has one of these in connection with the City Hospital, and another in connection with the public baths and the library. Chicago reports eight municipal tuberculosis dispensaries, quartered in new buildings, and Milwaukee has fourteen child welfare clinics, and is contemplating the erection of a special building for health centre and other municipal purposes. Washington has eight welfare stations conducted by the Child Welfare Society. Cincinnati has one general health centre, and Baltimore one and a day nursery.

The Boston health unit at 17 Blossom Street is suggested as a good, practical example of the type of building suitable for this purpose, with the understanding that each centre must be planned according to the demands of the section of the city in which it is located. The active medical and nursing associations at present doing work in various sections of Boston as parts of the health unit are the Boston Health Department, the Instructive District Nursing Association, the Baby Hygiene Association, the Boston Sanatorium for Consumptives, and the Boston Dispensary. To these must be added the various relief associations which render assistance to the poor and are necessarily closely allied to those alleviating diseases.

CHILD TRAINING FOR MOTHERS AND TEACHERS.

The increasing realization that educational methods of the present are sadly deficient and in many respects actually pernicious is creating a widespread interest in what can be done to remedy conditions. In some instances steps have already been taken toward the formulation and establishment of programs of endeavor along these lines by various institutions and organizations, and by individuals who feel that the chief hope for this demoralized world of ours lies in the clear thinking of the coming generation. Toward this end a comparatively new institution, the National Kindergarten and Elementary College, of Chicago, is working. The young women who attend this college work with the children themselves, not with barren pedagogic theory alone. The earliest grades are those of the prekindergarten or nursery age. This department of the school is conducted according to a modification of the English nursery schools, established for years in that country and recognizedly successful in caring for children of two or three, who must otherwise be left by working mothers to the mercies of small brothers or sisters, or to an already overbusy neighbor mother. In the kindergarten and elementary courses of the college, instruction is given in psychology applied to children, in playground and recreation work, care and hygiene of the child, educational method and procedure, as well as in the recognized academic subjects. The principal aim of the college, and that toward which all the work is directed, is to discover the individual and special ability or abilities of a child and to develop these in the most practical and constructive manner possible, so that the child may start life without that handicap of so many of the children of the past and even of today—a careless and defective school training.

VOCATIONAL GUIDANCE IN ALSACE AND LORRAINE.

Assisted by and at the instigation of employment offices, employers' and workers' organizations, chambers of commerce, school physicians and others, the Strassburg Chamber of Crafts has organized in Alsace and Lorraine a regional vocational guidance service, according to the *International Labor Review*, published in Geneva. Parents and children still attending school are urged to come to this service for advice, with the result that within the sixteen months between February, 1921, and June, 1922, sixty per cent. of the children about to leave school applied to the vocational guidance centre. The school is required to report concerning each apprentice the subject he likes best, the subject he dislikes most, statements as to his attention and memory, and the kind of mental work he has done and how he has done it. A medical report from the school doctor is required, giving the results of a detailed medical examination of each applicant, and the physician is also required to give his opinion as to whether or not the child should take up the occupation he wishes to follow. A psychological examination tests the child's senses. The vocational adviser then consults a file of monographs prepared by the Strassburg office from data furnished by industrial associations and indicating the qualities necessary to becoming a high grade workman in the various occupations. The advantages and disadvantages of the various occupations in regard to different temperaments are also discussed in the monographs, as well as the best age to start, the duration of the apprenticeship, the supply and demand, the compensation and chances for advancement. The vocational adviser must also consult the market before making his recommendation in order to acquaint himself with conditions of oversupply and shortage. Upon receiving a certificate from the adviser, stating that the prospective apprentice has the requisites for success in a given occupation, the young person calls at the regional employment office, which proceeds to try to locate him in a firm where he may serve his apprenticeship.

News Items.

Harvey Lecture.—Dr. Béla Schick, Professor of Pediatrics, University of Vienna, will deliver the fifth Harvey Society Lecture at the New York Academy of Medicine on Saturday evening, January 27, 1923. His subject will be The Prevention of Diphtheria.

Bronx Hospital.—At the regular meeting of the Medical Board of the Bronx Hospital and Dispensary held on December 28, 1922, Dr. William J. Robinson and Dr. Martin Rehling were reelected president and secretary respectively of the medical board for the twelfth successive year.

Heliotherapy Course.—Dr. Rollier will repeat the course on Heliotherapy usually given in summer at Leysin, Switzerland, January 16 to 21, 1923. This course is conducted by Dr. Rollier and his colleagues free of charge for the medical profession and was described in full in the *Journal of the British Medical Association*, October 21, 1922.

Fourth Harvey Lecture.—The fourth Harvey Society Lecture which was to have been delivered at the New York Academy of Medicine, Saturday evening, January 13, 1923, by Dr. William T. Bovie, assistant professor of biophysics, Harvard University, on The Physiological Effects of Light Rays, has been postponed until January 20th.

The American Medical Association Convention.—Will be held at San Francisco, Cal., June 25 to 29, 1923. The subcommittee appointed by the secretaries of the medical societies of the Eastern States have arranged a twenty-five day tour to San Francisco and return, stopping at interesting and important points. In order to make this tour a success it will be necessary to have at least 125 members subscribe to the tour. The State medical societies of the Eastern States and of some of the Middle States have appointed the following subcommittee to arrange for the tour: Dr. Edward Livingston Hunt, Dr. Wilbur Ward, and Dr. Malcolm C. Rose. The committee extend to all who contemplate attending the convention a cordial invitation to join the tour, communications to be addressed to Edward Livingston Hunt, M. D., secretary, Medical Society of the State of New York, 17 West Forty-third Street, New York.

LONDON LETTER.

(From our own correspondent.)

LONDON, *December 10, 1922.*

INSANITY AND THE LAW.

What is the definition of insanity? On the satisfactory answer to this question depends any amendment it may be found possible to make in the British criminal law relating to the position of insanity. Such was the general trend of discussion which took place at a meeting of the Hunterian Society in London a few evenings ago when Dr. Porter Phillips, the resident physician and Superintendent of the Bethlem Royal Hospital for the Insane, one of the largest, oldest and quite the best known in this country, read a paper on "The Position of Insanity in Criminal Law." Dr. Phillips argued that the law regarding criminal responsibility was unsatisfactory and, although eminent jurists had dealt with different aspects of the problem, little or no advance had been made. His own opinion was that the Crown in every murder case should appoint an independent tribunal to consider the medical side, having powers to investigate fully the mentality of the accused person. In that way the reliability of the medical opinion would be overwhelming, and would, no doubt, justly influence the opinion of the jury.

Dr. Hislop, speaking from twenty-five years' experience at Bethlem, said that he had come to the conclusion that knowledge of what was right and wrong was about as strong inside that institution as it was outside; therefore the test of responsibility depending upon a knowledge of right and wrong was fallacious. The law was loath to accept the fact that a person might lose all control without being legally insane, and the question of responsibility was always banned when a medical witness attempted an explanation. As an instance of the unreliability of juries he told the story of a man who was charged with a murder at Limehouse. It came out in evidence that the man had been seen creeping under the bed, and the jury, coming to the conclusion that no man in his senses could do a thing like that, promptly accepted the plea of insanity. "The man afterwards told me," said Dr. Hislop, "that he had dropped a tanner (sixpence) and was looking for it under the bed."

Sir Richard Muir, in the course of a survey of the law relating to insanity, said that the question of the practical application of the criminal law to persons suggested to be insane was one for which both the legal and the medical professions had endeavored to find solutions for a great many years. The legal profession was desirous of acquainting itself more thoroughly with the medical view, and would be ready at any time to accept a satisfactory definition of insanity; but, so long as they had trial by jury, they must have some working rule which would be understood by jurors. He was willing to learn from the medical profession how to apply rules so as to march with the advance of medical science, and the legal profession was willing to listen further to any possible amendment which could be suggested, but it must be an amendment which could be applied by a jury and understood by a jury. "That is the problem," concluded the speaker. "Find some definition of insanity which is satisfactory to you, which will be a protection to the public and which can be understood by a jury, and certainly the legal profession will not stand in the way of its adoption."

MILK.

Professor Eustace Hill, the president of the Society, said that in England the average daily consumption of milk per head was only one fourth of a pint according to a recent publication of the ministry of health, in contrast with the one pint in America.

Dr. W. J. Howarth, M. O. H., City of London, said he could not share Professor Robertson's confidence of the preeminence of America's milk supply. Dr. Howarth, who is not a believer in pasteurization as a safeguard of milk, said he hoped that so long as pasteurized milk is sold in Great Britain, it will be labeled as such, and receive no sort of commendatory recognition from the ministry of health.

Dr. W. Butler said that, as long as he had been a member of the Society, medical officers of health had been consistent in their demand for a pure milk supply, and he hoped that they would never be content with pasteurization as a substitute. A clean milk could be safely consumed in the raw state, and even the percentage of tuberculous milk had been enormously reduced.

Professor Robertson, in reply, said that his visit to America had overturned all his preconceived views as to the superiority of clean, raw milk; that it had been proved to him in America that pasteurization requires clean milk, if it is to be successful. The effect of pasteurization on the reduction of infant mortality had been remarkable in America, and he believed that even the inefficient pasteurization practised in England had been one of the great factors in saving infant lives during recent years.

HOSPITAL ALLIANCE.

The scheme just adopted between Middlesex and St. Luke's Hospital is stated to be the first instance in this country of an alliance between a large general hospital and a registered hospital for mental diseases. By cooperation in respect of funds, material, personnel and experience in management, the two hospitals are expected to attain the ideal in the treatment of early mental and functional nervous disorders while securing greater economy. Two new wards, for male and female inpatients, would be established in Middlesex Hospital, where patients will be treated by the medical staff of St. Luke's Hospital. A special outpatient clinic would be established for dealing with borderline cases, which would practically constitute a psychiatry section of the neurological department. So far as outpatients are concerned the scheme involves close cooperation of the two hospitals, and is a step towards a system which can and may be extended with advantage in other directions. As was stated in the report of the Court of Governors of the Middlesex Hospital, among the chief reasons which led to the adoption of the scheme was the marked disinclination among persons suffering from early mental disorders to consult the specialists at a hospital known to deal only with mental diseases. Such people were far more likely to attend at a general hospital for treatment on the appearance of their first symptoms. Early treatment on the right lines went a long way towards effecting a cure; delay was dangerous, or even fatal, to a successful issue. Treatment at a general hospital, also, did not attach the stigma which is popularly connected with a hospital dealing only with mental disease. In this way certification might be avoided.

INTESTINAL STASIS.

A discussion has been opened by Sir W. Arbuthnot Lane, who described his theory as to the cause of intestinal stasis, which in his opinion brought about directly or indirectly diseases of the colon. As is well known, the stasis, according to the views of Sir Arbuthnot Lane, is a result of the formation and development of kinks and bands in the colon. Sometimes operation was necessary but we wished to lay down with all possible emphasis that in such cases no operative procedure was justifiable until prolonged medical treatment had failed. Sir Henry W. Gray, of Aberdeen, could not agree with Lane about the formation of these bands being due to constipation and strain. Nor could there be any ground for the evolutionary theory, for these bands were never of any value for supporting the gut. Dr. A. J. Walton, of London, emphasized the marked increase in frequency of these conditions. He agreed with Sir Henry Gray that they were all of developmental origin and thought that eighty per cent. of those that showed symptoms were women. Symptoms did not appear until there was some ptosis. With regard to treatment he wished to draw attention to Lane's oft repeated teaching, that the treatment was essentially medical and operation was a last resource. He never fixed viscera unless symptoms pointed to one viscus, and even then he warned patients that they would not be absolutely cured.

BRITISH HOSPITALS.

It has been argued by some, and especially by those who have had any experience of American hospitals, that in order to relieve the financial strain upon British hospitals the system of pay wards should be introduced. In this country, however, change comes slowly and the doctor and layman alike in this country are wedded to the voluntary system by which such magnificent work has been done in the past. Yet it is recognized that steps must be taken to place the hospitals on a sound financial basis. Some of the hospitals are giving a tentative trial to the pay system. For example, somewhat longer than a year ago two of the wards of King's College Hospital which had been closed for lack of funds were opened for the use of private patients. A third ward was then required, and arrangements have been made to open a fourth in the course of a few weeks. Thus there seems to be no valid reasons why the system should not be introduced on a wide scale, although of course there are many difficulties to be overcome.

DEATHS FROM MEAT PASTE.

An inquiry opened at Drugwall, Scotland, on September 5th, into the eight deaths which occurred at Loch Maree as the result of eating meat paste. Professor I. K. Monro and Dr. W. E. Carnegie Dickson, who happened to be staying in the neighborhood, gave evidence at the inquiry. Monro expressed no doubt that the deaths were due to botulism and the other medical witnesses agreed with this opinion. Monro and Dickson both considered that little assistance would have resulted from the employment of antitoxin had it been available, and Dickson expressed the opinion that the damage to nervous tissue was already too far advanced. The pathological and bacteriological investigations are being conducted at Bristol. More than a year ago the Ministry of Health and the Medical Research Council combined to make arrangements for the fuller investigation of the conditions which cause sickness brought about by the various forms of bacterial food poisoning. It was further arranged that the investigation should be conducted in the laboratories of the University of Bristol. As the Scottish Board of Health came last year into the scheme the specimens from the Loch Maree cases were sent to Bristol.

EMPLOYMENT.

Statements recently made concerning the long hours and unsatisfactory conditions of employment of female assistants in eating houses in London, particularly in the southeastern district, have been specially investigated by the County Council Public Control, and they are satisfied that, apart from minor irregularities, there is no serious ground for complaint. In the smaller shops the provisions of the Shops Act, 1912, are generally adopted and the assistants are employed from sixty-eight to seventy-two hours a week.

MEDICAL MISSIONS.

A recent exhibition afforded proof if such proof were required, of the efficiency of the medical missions and of the good done by the workers therein. It should be stated that the men engaged in medical missionary work are men of the highest qualifications and it may be further said that practice in tropical countries is instructive and interesting in the first degree. Especially are there splendid opportunities for original research and the discovery of the causes of obscure diseases with the hope of finding out preventive, remedial and curative measures. Unfortunately at the present time, the medical staff of the missions is so inadequate that there is not time to attend to the sick and injured properly, and, of course, no time whatever for research. In fact, the deficiency of workers is a more serious impediment to work than a deficit of funds. However, if the work that has been accomplished in face of an almost paralyzing deficiency of staff and overwhelming financial deficit, a marvellous record is found. Forty-two thousand, eight hundred and sixty-three in patients have been admitted to the mission hospitals, 925,059 out patient visits have been attended to and more than thirty-six thousand operations have been performed. The missionary nowadays is a bodily as well as a spiritual healer and each of the mission hospitals constitutes a block house against epidemic disease and is for the good of the whole world. As a career while a position on a medical mission staff does not hold out the promise of gain or of greatness, it does offer a life of adventure spent in relieving sickness and in endeavoring to conquer disease.

Book Reviews

SURGERY OF THE EAR.

Handbuch der Speziellen Chirurgie des Ohres und der Oberen Luftwege. Mit Textabbildungen. Von Dr. L. Katz und Prof. Dr. F. Blumenthal. II Band, Lieferung 7. Leipzig: Verlag von Curt Kabitzch, 1922. Pp. 367-478.

This number (fasciculus 7, volume 2) of the Katz-Blumenfeld System deals exclusively with the operative opening of the mastoid antrum. The introduction gives a short historical survey of the origin and development of this surgical procedure. The chapter on diagnosis includes the bacteriology and pathological anatomy of acute, subacute and chronic otitis media purulenta. A comparatively long section is devoted to a thorough résumé of the indications for the mastoid operation and the interpretation of local findings as well as of constitutional symptoms. The details of the operation itself are then considered at length, including preparation, surgical technic, exposure of field, topography, hemostasis, and the special steps in the exposure of the sinus and dura. There are short but instructive sections on operations on the extremely aged and on hemophiliacs, relapsing mastoiditis, hypostatic abscess, aftertreatment, reinfection, keloid scar, change of dressings, plastic exposure of postauricular fistula, and so on.

THE HEART.

The Heart as a Power Chamber. Illustrated. By Harrington Sainsbury, M.D., F.R.C.P. Oxford Medical Publications. London: Henry Frowde and Hodder & Stoughton, 1922. Pp. xxi-248.

The title of the book commands interest and approval, emphasizing as it does the dynamics of the circulation. Medical studies, both physiological and clinical, have in recent years been devoted predominatingly to the cardiac irregularities and to their mechanism. It is time that the single track medical mind revert to the consideration of the dynamic and physical factors involved in the maintenance of the blood flow. The author is to be commended for emphasizing this important phase of circulatory disorders.

A perusal of the book, however, leaves the reader unsatisfied because so many important aspects of the subject have not been touched upon. Moreover, the author is often hampered in a clear presentation of his subject by the teleologic twist which he gives to all of his observations and speculations. Theories that attempt to explan phenomena as planned by Nature for a purposeful act are rarely fruitful. It is characteristic that in such a book experimental findings are made a subchapter, appended to a philosophical consideration of the facts under review. The elementary facts of the dynamics of the circulation are adequately presented. The author, however, disagrees with the present view that back pressure effects are relatively unimportant in producing myocardial insufficiency with its resultant symptoms and questions the current interpretation of venous tracings. His criticism is not always convincing, and he offers no adequate alternative explanation. One is astonished to find no mention of the fundamental work of Starling and his associates on the socalled "law of the heart." The employment of phrases such as "the katabolic heart," for the senile heart, is unfortunate and may be traced to the same liking for teleological reasoning. The real value of the book lies in drawing attention to the importance of the study of the dynamics of the circulation.

THE GALLBLADDER.

Studien über die Funktion der Gallenwege unter normalen und gewissen abnormen Verhältnissen. Acta Chirurgica Scandinavica, Supplementum ii. Von Dr. John Berg, Stockholm: Kungl. Boktryckeriet, P. A. Norstedt & Söner, 1922. Pp. 185.

In this, the third monograph on the subject, the author combined the clinical and pathological—anatomical studies of histories and specimens of gallbladder cases treated surgically, so as to obtain a clearer insight into the histologic basis, symptomatology and etiology of the socalled phenomenon of biliary stasis in the bile passages. The purpose of this work was to draw conclusions concerning the moot question of the normal functions of the biliary passages from the observations on the phenomena of stasis. The author believes that he has secured an additional aid for the differentiation of two different kinds of stasis in the biliary passages and also that the newly acquired material enables him to separate a group of sequelæ of uncomplicated, extrahepatic biliary tract forms and functional types, which he includes in the term rudimentary forms, from the true forms of stasis.

The subjects of mucostasis and cholestasis are discussed in their clinical, pathological, diagnostic and therapeutic aspects most thoroughly. This view of the subject also gives an impression of greater clarity in regard to the genesis of biliary calculus formation. As a result of the more thorough study of the pathology, as instituted by the author, the therapy is established on a more rational basis and the basis of prophylaxis is established more firmly. Besides aiding in a clearer understanding of the subject, with reference to the entire organism, it is a distinct improvement on the older methods of considering the subject. The detailed histories of sixteen cases, together with illustrations of the gross and microscopic lesions, are given.

ANIMAL PARASITES.

Animal Parasites and Human Disease. By Asa C. Chandler, M.S., Ph.D. Second Edition, revised. New York: John Wiley & Sons, Inc., 1922. London: Chapman & Hall, Limited.

Until one reads this most interesting and well-written book, one can hardly realize how many animal parasites may infest the human body. The author has considered these pests under the three great divisions, protozoa, worms, and arthropods, and he has made his work attractive enough to fascinate the reader like a best seller. He emphasizes the fact that the progress of sanitation and the betterment of health in general have been held back by unprogressive physicians and quacks who wilfully or ignorantly refuse to consider ways and means of destroying these innumerable parasites which so often destroy human life.

He cites in detail the history of the Panama Canal

Zone as convincing proof of the practical value of the knowledge which has come to us regarding the relationship between the mosquito and malaria. Almost despairingly he bemoans the fact that today, one hundred and twenty years after Jenner, there are numerous antivaccination societies whose sole purpose it is to denounce vaccination against smallpox, and he asks how we can expect popular belief in the mosquito transmission of malaria which was demonstrated only twenty years ago.

What is perhaps the most startling chapter in the book is his consideration of the subject of syphilis and its prophylaxis. Braving the wrath of the purists and the professional social hygiene workers, the author dares to express the view that "the most feasible plan, at present, as successfully tried in many European cities, especially Germany, is the municipal supervision of restricted 'red light' districts"; but he certainly is on solid ground when he declares that "the abolition of 'red light' districts is invariably followed by a parallel increase in clandestine prostitution, luring many who would abstain from unmasked brothels, to say nothing of the increase in seduction and rape of innocent girls." We venture to predict some disagreement from these views from highly influential sources.

Throughout the entire volume there is an atmosphere of sanity and clear thinking backed up by a thorough knowledge of the subject under discussion. The style is lucid and entertaining, and the reader passes from page to page and chapter to chapter fascinated by the marvels of Nature as exhibited by these minute enemies of mankind. The illustrations are plentiful and well drawn. Altogether the author is to be complimented on his excellent presentation of an otherwise dull and dry subject.

DISEASES OF WOMEN.

Diseases of Women. By HARRY STURGEON CROSSEN, M.D., F.A.C.S. Fifth Edition. Revised and Enlarged. With 934 Engravings, Including One Color Plate. St. Louis: C. V. Mosby Company, 1922. Pp. xxiii-1005.

This edition has been entirely reset and revised, bringing the entire subject up to date. Many of the newer developments in röntgenographic diagnosis are described in detail, such as abdominal and pelvic pneumoperitoneum after intrauterine insufflation of gas. The subject of x ray and radium therapy in uterine cancer, myoma, and other pelvic conditions are also discussed.

Pathological considerations are emphasized, particularly the subjects of more recent investigation, such as the changes in the endometrim, subinvolution of the uterus, adenomyomas and the part played by ovarian endometrial cysts. Actual photomicrographs are introduced to show the microscopic anatomy and pathology, thereby securing a complete survey of the tissue and condition involved. The pathological illustrations are excellent.

Gynecological diagnosis should be both anatomical and pathological, and that is the plan followed throughout this book. The headings and subheadings are arranged in such a way as to make this work an ideal reference book. The various symptoms encountered are also discussed in detail.

The chapter on therapy includes the various methods of treatment and their indications, with minute details regarding the carrying out of the treatment, each therapeutic remedy being treated separately, in addition to the treatment indicated in the various diseases and conditions, where the older plan of giving anatomy and pathology, symptoms, diagnosis and treatment is followed.

In the chapter dealing with the relaxation of the pelvic floor the newer methods of repair, aiming at the anatomic coaptation of the deeper parts, as well as the older methods are given. The more recent and improved methods of repairing the cervix uteri are fully described. Much space is devoted to the use of pessaries in displacements of the uterus; the operative measures, their advantages and disadvantages, are clearly indicated by a tabular arrangement. The use of x rays and radium and their indications and contraindications in myoma uteri are clearly given, the operative measures not being neglected. Separate chapters are devoted to malformations and disturbances of function, respectively.

The section on the endocrine glands was written by Hugo Ehrenfest. Special chapters are also devoted to the subject of the relationship of other organs to gynecology, the surgical invasion of the peritoneal cavity, including general surgical considerations and technic, the surgical aftertreatment and the medicolegal aspects of gynecology.

On the whole, this is an ideal book to place in the hands of medical students and practitioners: it is complete and up to the minute. The pathologic elements of disease are stressed more than in any previous book on the subject.

THE IMPULSE DRIVE.

Impuls-Handlungen. von DR. WILHELM STEKEL. Mit 4 textabbildungen. Berlin und Wien: Urban & Schwarzenberg, 1922. Pp. ix-520.

Stekel is always interesting, always voluminously instructive. He always offers a challenge to the individual reader to consider and to make trial of the psychoanalytical method for which he claims his large results. There is a challenge also to the acceptance or not of some of his own modifications of such method and of the theories with which he supports these. There is, too, a certain resonance of his own personal superiority accompanying the exposition of his material which makes one often distrustful of his claims to first discovery or alteration of some of the points of view of the older school of psychoanalysis. This casts uncertainty about the validity of some of his criticisms of their theories and activity. Aside, however, from such rather conspicuous and yet minor faults in his writings, his series of books constitutes a valuable contribution to the attested work of psychoanalysis. It brings understanding of certain special phases of the unconscious life and the forms in which psychopathology finds it manifested. He offers in all this and particularly in his pointed summarizing of his matter a challenge to society which it may not pass by. For while he attempts to understand his matter from the standpoint of the sick individual he no less lays its own share of the burden of the psychoneuroses, parapathies he chooses to call them, upon society's attitude toward the individual. He points out that the impulsive actions which society is prone to look upon only as criminal belong in the last analysis to the maladjustment represented by the parapathies and thus that crime or criminal actions are first of all curable as individual illnesses. The responsibility of society shall not cease until it has found them so. With a characteristically large optimism based on many unpleasant but adjustable facts he looks toward the day when such shall be common opinion and practice.

The title of the book informs us as to the specific content of this volume. Here as in the previous volumes Stekel has discussed the phases of his subject as he has found these in the lives of his patients, tracing them there in the unconscious in order to understand them from that standpoint out toward their external manifestations. Thus he finds the impulsive actions formed of the entangling infantile complexes with a significance and a possibility of readjustment undiscovered by the merely conscious observer.

Stekel's work is full of detailed material of actual clinical value. He makes free use of comparison with the points of view of other workers and thinkers upon these subjects. His style becomes rather over discursive as he supplements his own detailed case histories by likewise detailed reports from other writers. Yet his style is always so clear that one may gain knowledge and stimulus from any one portion of the book or from a more careful reading of the whole.

BODY NEEDS.

Einige neuere Betragtungsweisen in der Ernahrungstherapie. VON PROF. DR. ALFRED GIZON. Halle a.S: Verlag von Marhold, 1922.

Gizon considers the minimum amount of protein required by the body for twenty-four hours to be about one gram to one kilogram weight, or on an average sixty to seventy gm. of protein per day for an adult. Gizon thinks it best not to give patients much more protein than the minimum requirement. The reason for this is the great demand made in the working up of proteins on the work of the liver, kidneys, and the intestine. Gizon considers olive oil as a good fat nutriment and of much benefit in hyperchlorhydria and peptic ulcer; he gives one to two teaspoonfuls of olive oil three times daily before meals. Olive oil diminishes the gastric secretion, and, if taken in the fasting condition, accelerates gastric motility. The monograph is well written and contains much useful information.

BRAIN ABSCESS.

Brain Abscess. By WELLS P. EAGLETON, M.D.Lt.Col., M.R.C. New York: The Macmillan Company, 1922. Pp. xix-297.

The highly specialized domain of brain surgery will be enriched by the addition of this work. With great frankness the author has presented his failures and this material becomes of value when we consider that in every instance he has sought for their explanation and for a perfection in the technic of procedures both diagnostic and operative. The work has been carefully done. The author's own extensive experience in brain surgery, coupled with the study of a voluminous literature, adds to the value of the book. It is a workmanlike presentation of the labors of a man with sincerity and marked ability.

OPHTHALMOLOGY.

Ophthalmoscopy, Retinoscopy, and Refraction. By W. A. FISHER, M.D., F.A.C.S. With 248 Illustrations Including 48 Colored Plates. Published by W. A. Fisher, M.D., F.A.C.S. Chicago, Ill.

Fisher's manual, combining as it does a description of two of the most important methods of clinical examination of the fundus oculi with the estimation of ametropia, contains a great deal of information presented in a practical and easily assimilated way. It is not the author's fault that it is a physical impossibility to dispose of these far-reaching and by no means simple subjects in the space which he has devoted to them. Of ophthalmoscopy in particular, one may well say that Fisher's book will give merely a smattering to those who are beginners and will not be of much value to the expert. The illustrations are numerous and yet inadequate as they are rather schematic and on much too small a scale, while the descriptive text in many instances fails to explain, fully, the details of the fundus picture it accompanies.

PLAYS BY EUGENE O'NEILL.

The Emperor Jones; Diff'rent; The Straw. By EUGENE G. O'NEILL. New York: Boni and Liveright, 1921. Pp. x-285.

The Hairy Ape, Anna Christie, The First Man. By EUGENE O'NEILL. New York: Boni and Liveright, 1922. Pp. 322.

The first volume contains that momentous study of primitive psychology, that has held Metropolitan audiences entranced for over a season. Fear, the supreme god of the savage, is harrowingly pictured. The perspective given to the lines of The Emperor Jones by the stage setting, the acting, the personality of players and writers, makes this play a masterpiece of technic. The emotions of a neurotic, love starved woman, presented in *Diff'rent,* again cling to the memory like some brutal scene of which one has been the unwilling spectator. *The Straw* pictures in more normal fashion the way playgoers believe the mind works. The little heroine dying of tuberculosis and for want of the will to live, is saved by her lover at the tense last gasp.

Vignettes of the psychology of emotions are these, stark and unadorned. In the second volume theory, philosophy, a more subtle psychology creep in to make the plays the intricate spider web where our own emotions hang helpless. *The Hairy Ape,* striving to understand, lost, tongue tied mentally though not physically, begins the tirade against things as they are. *Anna Christie,* the strongest of O'Neill's plays since *Beyond the Horizon,* introduces two characters to contemporary drama that will live down the ages. Father and daughter in the eternal struggle of evasion and life finally drift to their inevitable end. *The First Man,* a social travesty on the emotions of parenthood, gloomily winds its Victorian coils in Bridgeport, Conn. This is the only one of the plays that is not good. There is lack of plausibility; the whispering mob of relatives that clings about the intrepid explorer seems overdrawn. It is all too ponderous.

To have these plays in book form is of inestimable value. All, even the last, merit careful study, appreciation. Mr. O'Neill's work opens up a hopeful future for drama in America.

PERSONALITY.

Up Stream. By Ludwig Lewisohn. New York: Boni & Liveright, 1922. Pp. 248.

The evolution of a personality has a magic of its own. That is the secret of the fascination of autobiography of every sort. But in Mr. Lewisohn's biography there enter factors distinctly unusual. The initial racial hindrance to his progress has been keenly studied, even his overcompensations recognized. The part played by his mother in his life reveals once more the power of unconscious patterning, the moulding of a man's destiny by the chance occurrences of the first few years of his life. *Up Stream* has achieved the goal of a novel. It transcribes life, with that blending of reality and fancy that colors all true romance. A sound book; a delightful piece of literature, and as entertaining as it is valuable.

THE BEE.

The Adventures of Maya the Bee. By Waldemar Bonsels. Illustrated by Homer Boss. New York: Thomas Seltzer. 1922. Pp. 224.

This airy phantasy is delicate, picturesque. It is a delightful bit of soap bubble creation. There is a little fact in it, details not too wearisome of the insect world. It is the eminently correct Christmas gift for the young child with sufficient insight into the facts of Nature not to have an attack of horrors from the discovery that insects eat each other.

Medicoliterary Notes.

A recent bulletin of the Department of Labor and Industry of Pennsylvania reports that, through the investigations of the Bureau of Hygiene and Engineering, the discovery has been made of a regularly established underground traffic in the use of second hand stuffing materials for upholstery, represented to buyers as brand new. Some of this material has been found to be filthy beyond description, and a haven for germs, insects and many kinds of refuse. Even floor sweepings are used to piece out short quantities.

* * *

Constantinople Today is the title of a book recently published by eight welfare organizations working in Turkey. It is the result of a survey of social and economic conditions in that country.

* * *

Joachim Sorolla, son of the famous Spanish painter, has arrived in this country with an exhibit of his father's pictures to be shown at the Hispanic Society, Broadway and 155th Street.

* * *

Steps are being taken by the Bowling Green Neighborhood Association, a welfare organization for poor relief in New York City, to wipe out the scourge of tuberculosis in a small area of the city near Wall Street, inhabitated almost entirely by the scrubwomen, porters, janitors, window cleaners and other workers who labor in the great downtown office buildings. It is reported that the death rate in this section from tuberculosis is three and a half times as large, and infant mortality double the average rate in other districts of New York. The association plans to make a survey of the neighborhood, with physical examinations and clinics, nutrition classes for adults and children are to be organized, literature in all languages to be distributed, and health plays and films shown. A permanent educational exhibit will be set up in the Community House at 45 West Street as a part of the antituberculosis campaign, and complete statistical records kept.

* * *

Abnormal Behavior, by Dr. Phyllis Blanchard and Dr. Irving J. Sands, has been announced for publication by Moffat, Yard & Co.

* * *

The physician who is interested in social, economic, the psychological problems will find a great deal of food for thought in *The World We Live In,* familiarly known as the "insect play." It is perhaps the most original in conception, and certainly one of the most revealing of the dramas now on the boards.

* * *

The American Committee for Devastated France has announced that it will build and administer for a limited period the first modern training school for nurses in France in connection with a hospital being enlarged by Dr. Oberthur of Paris. A year's investigation has recently been made by a group of Americans interested in nursing and public health, as a result of which Professor Calmette, of the Pasteur Institute of Paris, at the head of a group of representative French physicians, formally requested the committee to establish a model nurses' training school. Under the leadership of Dr. C. E. A. Winslow, of Yale University, a committee was formed to do the work, and three young French women have been in training in the United States for several months to become qualified to carry on later the work in their own country.

* * *

In an entertaining article in the *Atlantic* for December, Elizabeth Stanley Trotter writes on Humor with a Gender, a discussion of the differences in the sense of humor between men and women.

* * *

The works of Arthur Machen, the Fleet Street English journalist whose stories have only recently reached this country, will soon be published complete in a nine volume edition. Some of the best known of these are *The Great God Pan, The Hall of Dreams, The House of Souls, The Terror,* and *Hieroglyphics.* To the psychoanalyst interested in the psychology of fear and of the sense of sin and in symbolism these tales should be significant. Another book in which he will find entertainment is the second volume of Harvey J. O'Higgins's short stories based on studies of various American types.

New Publications Received.

GONORRHEA AND IMPOTENCY. Modern treatment. By Edwin W. Hirsch, B.S., M.D. Chicago: The Solar Press, 1922. Pp. 12-172.

THE DIAGNOSTICS AND TREATMENT OF TROPICAL DISEASES. Illustrated. By E. R. Stitt. Fourth Edition—Revised. Philadelphia: P. Blakiston's Son & Co., 1922. Pp. xiii-622.

Practical Therapeutics

THE THERAPEUTICS OF SURGICAL PAIN.

By John Hubley Schall, M. D., F. A. C. S.,
Brooklyn, N. Y.
Surgeon, Prospect Heights, Jamaica and Community Hospitals.

The efficiency of any specialization in medicine is seriously hampered if the maxim, "be a physician first and then a specialist," is not rigidly observed. Physiological relationships should not be neglected, or considered secondary to anatomical ones. The study of physiological pathology is receiving more consideration, and its study is as indispensable in surgery as elsewhere.

The inaccessibility for inspection of many organs, except in limited and welldefined instances by the x rays, has accorded the important symptom of so-called pain a valuable diagnostic significance in surgery.

There are four important classes of cases associated with pain that require relief by the surgeon. 1. Pain appearing as a symptom for surgical diagnosis and operative intervention. 2. Pain having existed for some time where operation is indicated, but necessarily must be delayed for diagnostic purposes or operative risk. 3. Postoperative pain. 4. Pain in inoperable cases and the moribund from surgical affections.

The management and treatment of the first class of cases calls for surgical judgment to a degree not required in the other divisions. It places upon the surgeon the responsibility of furnishing relief without at times masking the only signpost leading to a correct diagnosis. It cries both for and against narcosis. It has demanded the lesser of the two evils, that of furnishing relief with morphine or one of its derivatives, or allowing the patient to suffer some pain for the purpose of ultimately saving his life. It is better to allow acute abdominal pain with a diagnosis of appendicitis, operation and recovery, than bring about a narcosis, a ruptured appendix, pus in the abdominal cavity, peritonitis, and death. Therefore while the diagnosis is pending, we have needed a drug which would cause a state between analgesia and narcosis.

The time required for a full history, complete examination, and the results of various tests, frequently demands more or less suffering on the part of the patient. Any of the following conditions, among others, may be responsible for the abdominal pain, which may be taken as a surgical prototype for our consideration: Acute indigestion, cholecystitis, ovarian or tubal disease, pneumonia with referred pain, intestinal colic, acute interitis, typhoid fever, gastric ulcer, dysentery, pancreatitis, hepatic colic, intestinal obstruction, renal colic, movable kidney, ureteritis, epididymitis, dysmenorrhea, lead poisoning, hipjoint disease, incipient inguinal hernia, malignant tumor, pleurisy, Pott's disease, cerebrospinal meningitis, abdominal crisis of locomotor ataxia, distention of the urinary bladder, hysteria and appendicular hypochondriasis. A mass in the right iliac region may be the result of fecal impaction, neoplasm of the structures in this region, especially the appendix and cecum, cysts, lymphadenitis, foreign body in the intestine, intussusception, cholecystitis with distention, aneurysm, abscess (from the vertebræ or pelvic bones, iliopsoas or abdominal muscles), pericecal abscess, pelvic cellulitis, inflamed undescended testicle, properitoneal hernia, displaced kidney, phantom tumor, and various other local or remote causes.

The second class of cases associated with pain comprise those where a diagnosis has been made and operations decided upon, but whose physical condition must first be improved, or those in whom pain has persisted for some time, and who are being kept under observation for diagnostic purposes. In this class of cases, not of the acute class, it is necessary to prevent the pain from interfering with the proper preparation of the patient for operation, and from lessening his resistance, thus decreasing the operative risk and assisting the postoperative convalescence.

The third class of cases, postoperative pain, interferes with the recuperative powers, delays convalescence, and adds a neurotic element or increases one already present. This is particularly the case in gynecological cases, where long continued invalidism has drained the resources before operations. This does not refer of course to unavoidable pain of more or less brief duration sometimes as a necessary sequel to abdominal operations, such as gas pains, but rather to pain from wounds, or surgical traumatism in hypersensitive cases.

The fourth class of cases are the inoperable ones, especially malignancy where operative interference is either contraindicated or futile, and where relief must be given. Notwithstanding the gravity and hopelessness in such cases it is certainly better at times to have means at our disposal whereby we can relieve the suffering of such a patient without the abolition of consciousness, especially in instances where impending dissolution may extend over a prolonged period of time.

Until recently the only means at the disposal of the surgeon where severe pain was a predominating factor consisted of morphine and its derivatives, either by mouth or more generally by hypodermic administration.

One of the most recent classifications of pain in surgical conditions and apparently a good one is that by Karewski (1), who comes to the conclusion that not only the cerebrospinal nerves but also the sympathetic nerves may cause pain in these organs. He differentiates four types of abdominal pain: 1. Colic caused by contraction of the walls of hollow organs which is purely organic pain and characterized by alternate remissions and exacerbations; 2. pain caused by distention of the intestines, which is continuous, not intense and is a sign of increased stenosis of the large intestine, which as a result of peristaltic adaptation does not cause colic; 3, general abdominal pain which indicates involvement of the parietal peritoneum and is characterized by the appearance of reflex tension of the abdominal wall; it is often distinctly localized but may be diffuse, especially in perforation of a hollow organ into the abdominal cavity; 4, perforation pain which is particularly severe, diffuse and continuous.

In order to fully realize the significance of pain referable to a given area, there are several additional factors to be taken into consideration. They are an understanding of the nerve distribution in the painful area, the significance of the character of the pain, its manner of onset, and any associated conditions such as vomiting, pulse and temperature changes, leucocytosis, and other indications. Furthermore, the psychological element should not be overlooked, especially in neurotic patients, as it is particularly in such cases that the morphine habit is later established.

The difficulty which had hitherto presented itself to surgeons was the absence of any intermediary therapy for the relief of pain, between a mild analgesia and narcosis. In severe pain the only choice appeared to be between a practical placebo or unconsciousness. Physiological doses had not yet been established for the relief of surgical pain. In other words, in order to lessen the noise of the telephone the central station had to be put out of commission. Severe pain could only be abolished by preventing its complete appreciation. There are degrees of central analgesia without the abolition of consciousness, and without the complete extinction of sensation, motion or reflex activity, as there are gradations of unconsciousness which are measured by the stimulus required to arouse the patient. The term so often expressed "partial unconsciousness" is of course a question of degree and not of kind.

The administration of an analgesic drug to any degree affecting consciousness is manifestly dangerous, while on the other hand narcotics are frequently not effective for analgesic purpose alone unless pushed to the point of a partial abolition of consciousness.

Our therapeutic nomenclature has been enriched, and our resources for the relief of pain due to surgical conditions pauperized by the interchangeable employment of hypnotics, narcotics, depressants, soporifics, somnifacients, and what not, eventually subscribing to the almost universally adopted routine of hypodermatic administration of morphine as a short cut to the desired goal. As a result diagnosis has been obscured, elimination retarded, and thousands of morphine habitues irrevocably consigned to lives of addiction and degradation.

There is a vast difference between the indications for narcosis in surgical operations and that for the relief of pain before or after operation. As yet we have had no satisfactory analgesic drug that could be given in safe doses where intractable pain and insomnia were present; nor could its physical admixture with opium or any of its derivatives produce a controllable product. To satisfactorily relieve the pain of an acute abdominal condition without narcosis has been one of the therapeutic problems of the surgeon. notwithstanding the studies upon the conductivity of pain.

We are indebted to Burns (2) for being the first to have called our attention to a new nonnarcotic drug which is both hypnotic and analgesic, and which promises through the successful researches in the domain of synthetic chemistry, to furnish us with a therapeutic lever to control analgesia and hypnosis, without involving the dangerous field of narcosis. This would not have been attempted without thoroughly recognizing the fact that the cause of an insomnia may be due to any of a series of courses from a mild nervousness to a severe pain, and that the production of sleep in one case cannot be approached in the same manner as that in another. For this reason it has been taught for years never to use morphine unless the insomnia was due to pain, nor has the large list of analgesics and hypnotics found favor for the relief of insomnia due to pain. This has been due to the fact that the predominating symptom-pain, unless controlled first, prevented the therapeutic efficiency of the hypnotics.

The new drug, allonal, described by Burns, appears to be the culmination of the accumulated investigations in the field of the barbituric acid series, drugs, which although valuable hypnotics, apparently have lacked the additional and indispensable requirement, at the same time to control the pain. As the result of a great amount of animal experimentation, supported by abundant clinical observation, a new barbituric acid derivation was selected as the starting point for the additional chemical incorporation of an analgesic molecule. The allyl-isopropyl-barbituric acid was therefore chemically combined with amidopyrin by fusion, producing a double salt, which exemplified not only potential analgesia but a fortification of the preexisting hypnotic properties. The biological and chemical inspiration that led up to these results, and the scientific basis from which the production of a drug developing simultaneously hypnotic and analgesic properties was evolved are fully described in Burns's article.

The brilliant results already obtained, as described by Burns, of Philadelphia, Dr. Frank Wright, of Chicago, Or. L. Stieglitz, of New York City, and Dr. A. C. Messmer, of Ardmore, Pa., constitute the pioneer investigations of allonal based upon a number of welldefined and acid tests for the relief of pain, which in some instances could not even be controlled by morphine. When I learned from such sources that these results were obtained in conditions such as carcinoma of the rectum, mucous colitis with exaggerated peristalsis, chronic cholecystitis associated with arteriosclerosis, incurable intercostal neuralgia, probably due to a neoplasm pressing on the nerve, tic douloureux, lightning pains of tabes dorsalis, pain in rheumatoid arthritis, melancholia with drug addiction, multiple neuritis, and cerebrospinal lues, I welcomed an opportunity for a clinical investigation.

The following will serve to illustrate types of surgical cases which came under my observation during the past year and where allonal was administered with gratifying results:

Case I.—Mrs. H., aged thirty, operated on for external and internal hemorrhoids. The pains were severe, spasmodic and paroxysmal in region of the sphincter muscles. Allonal promptly reduced pain and induced sleep in this patient. The pain of this class of cases usually is relieved only by hypodermic or morphine or opium suppositories.

Case II.—Mr. C., aged twenty-one, fractured rib with contusions and lacerations of intercostal muscle. After the usual surgical treatment, the patient was restless and unable to sleep. He had severe pain on the slightest movement of the body, also during respiration. Allonal relieved the pain and induced restful sleep.

CASE III.—Mrs. G., aged forty, carcinoma of the breast with involvement of axillary glands. A radical operation was performed. This patient had suffered considerable pain prior to the operation which was relieved by morphine. Two days after the operation morphine was discontinued and allonal given, which allayed the pain and induced sleep. In many of the more advanced cases of carcinoma I have found allonal a remedy *par excellence* for the relief of pain and general comfort of the patient.

CASE IV.—Mrs. G., aged thirty-eight. This patient had had a removal of her appendix and a central suspension of the uterus. Following the operation there was a retarded peristalsis, slight tympanitis, cramps in the abdomen and pains in the region of the uterine anchorage. The patient was restless and could not sleep. These postoperative symptoms usually call for morphine. Within half hour after receiving a dose of allonal the patient was relieved and a little later was sleeping quietly.

VACCINE THERAPY, THEORY AND PRACTICE.

By L. F. ROBINSON, M. D.,
Greenville, S. C.

Infections contracted during natural processes always start with small beginnings. A boil may start from a small focus of infection in a hair follicle. A coryza, mastoid or sinus infection starts from a small germ invasion. Pneumonia develops from a comparatively small number of pneumococci gaining entrance to the circulating blood. Wound infections are usually developed from a small number of germs that happen to get into the wound. A puerperal sepsis starts with small proportions. In contagious diseases it is not probable that there are many germs conveyed from the sick to the healthy to cause infection. Infections practically always start with a small dose of infecting organism. It is due to the susceptibility of the infected individual to the invading organism that makes an infection possible. The infection does not become established because there is an overdose of the invading organism but because the small number of organisms which establish themselves grow and multiply at the expense of the invaded tissues. If germs were adequate in antigenic influence in the early stages of an infection, tissue resistance from antibody production would develop long before destructive processes from the infection would have time to develop. In the early stages of an infection germ multiplication progresses rapidly. This shows that the infecting organism bears a relation of virulence towards the involved tissues. Virulence of an organism depends on rate of multiplication, and rate of multiplication depends on the effectiveness of the ferments which the germ secretes, with which it digests and prepares the food on which it lives. It is this digestive capacity of the infecting organism which exerts such a destructive influence on the living tissues. In fact, this destructive capacity of the living germ is so pronounced that instead of influencing cells for antibody production they are crippled in their defensive capacity, and from the course these infective processes pursue it is entirely probable that infecting organisms only become true antigens after their virulence has become modified during the course of the infection. Naturally, the earlier in the course of an infection tissues can be influenced in their defensive capacity by germs of the same kind that are responsible for the infection that have been modified in their virulence (true antigens) the sooner will immunity become established.

This is exactly what is accomplished by giving a vaccine in the early stages of an infection. In the early stages of acute infections the invading organism is too virulent to exert a proper antigenic influence. By injecting killed germs into healthy tissues, cell activities are at once roused to dispose of or eliminate them. The germs being killed, possess no destructive influence nor can they increase their toxicity by growth or multiplication. Their toxicity is modified and consequently they possess true antigenic properties in relation to the tissue cells with which they come in contact. Possessing identical biochemical constituents to the organisms responsible for the infection, the antibody produced as a result of the killed organism injection is the same as the antibodies that may be developed from the antigenic influence of the live organism in the infected area, and consequently has the same destructive influence on the invading live organisms with the advantage of obtaining rapid antibody formation in the early stage of the infection and by this means eliminating the infection before destructive processes have time to develop. In other words, by injecting killed organisms or bacterial vaccines we obtain real antigenic influences to bear on the infective process before the infecting organism becomes sufficiently modified as a result of its environment to become an adequate antigen.

In case this modification of an infecting organism towards becoming a true antigen develops slowly, or is arrested, the infection will become chronic. Some infecting organisms are distinctly inclined to producing chronic infections. As a rule, these organisms do not show special virulence in the early stages of the infection, but the infection has a tendency to drag on. This is particularly true of the gonococcus, staphylococcus and certain types of the streptococcus. In these infections the antigenic properties of the live organisms are limited and often almost nil, whereas the killed organism of the same variety when injected into healthy tissues, shows marked antigenic properties as demonstrated by the clinical results obtained.

In the application of bacterial vaccines for therapeutic immunization the proper dose is of utmost importance. Infections present, broadly, three conditions: Extensive acute infections, minor acute infections, and chronic infections, and in each of these conditions the dose and interval between inoculations varies greatly.

In extensive acute infections, associated with much rise in temperature and other toxic disturbances as in pneumonia, bronchopneumonia, erysipelas, scarlet fever, puerperal sepsis, pelvic cellulitis, extensive wound infections, and other conditions, large doses of vaccines are tolerated without causing any appreciable reactions, either in rise of temperature or infiltration at the site of inoculation. Inoculations are made at short intervals to great advantage. The adult initial dose is four or five times that usually employed in chronic infections or one mil. (c. c.) of an average stock vaccine, inoculations being made at daily intervals. As a rule, if the vaccine is given early in the course of the infection, marked clinical improvement will be observed within twenty-four hours, but inoculations should be made at daily intervals for at least three injections. If the temperature has meantime become normal, injections are extended to two day intervals and as recovery advances they are made three or four days apart, but should not be discontinued until all signs of the infection have disappeared. Patients with severe infection should receive one mil. doses twice daily for one or two days and at longer intervals after the temperature, pulse and other clinical symptoms show definite improvement. If, after the temperature has returned to normal it rises again one or two degrees, this would indicate a falling back of immunization and would call for another injection, especially so if no vaccine has been given for several days.

Minor acute infections, like colds, acute otitis media, slight wound infections, boils, and similar conditions, require a small initial dose, about 0.2 mil. or three minims of the usual stock suspension, and the dose should then be increased in accordance with the reaction that developed from the first injection, inoculations also being made at short intervals, from one to three days apart. If one mil. doses are given in these cases unpleasant local and constitutional reactions are liable to follow and the clinical results are not so good as when the dose is so gauged that marked reactions are avoided. As a rule, the dose may be increased to one mil. within four or five treatments, but if considerable infiltration develops at the site of inoculation it is not wise to materially increase the subsequent dose even if a number of small doses are given in succession. As a rule, it is not necessary to work the dose beyond one mil.

In chronic infections we have two kinds of reactions from the use of vaccines focal at the site of infection, and local at the site of inoculation. For this reason treatment should be started by giving a small dose and the dose should not be repeated until all signs of reaction from the previous dose have subsided, which is usually a week. More failures from the use of vaccines in the treatment of chronic infections are due to overdosing and giving them at too short intervals than from all other causes combined. I am frequently consulted for advice in the treatment of cases that do not progress favorably, and almost invariably it is found that too large doses were employed, the vaccines were given at too short intervals, or both. The best immunizing responses are obtained if only a slight reaction develops at the site of injection, the infiltrated area not being larger than a silver dollar. If an inflammatory area develops three or four inches in diameter, the tissues at the site of injection appear to be severely taxed and consequently not so capable of antibody production, a condition similar to that which prevails in an infection, but by gauging the doses to produce a moderate reaction the maximum immunizing response is obtained. As long as this fundamental condition for producing immunizing responses, from the hypodermic use of bacterial vaccines, is not recognized in the treatment of chronic infections by the practicing immunologist, the best results from the use of vaccines will not be obtained.

The greatest advances in the prevention and cure of disease have been brought about through immunization. The use of bacterial vaccines in the more common infections, is both prophylactic and therapeutic; prophylactic in that the infection is brought under control, and in this way prevents more serious diseases, and therapeutic in that the existing infection is more rapidly eliminated.

714 West Washington Avenue.

Two and a Half Years' Antenatal Work.—Mary E. Weston (*British Medical Journal*, May 27, 1922) shows the great value of the antenatal clinic as an educational factor and its possibilities in preventive medicine among the socalled normal cases of pregnancy. Forty per cent. of women out patients suffer from some form of ill health directly or indirectly due to pregnancy, which are the result of neglect of the socalled minor maladies. Their prevention is a matter of individual teaching, to be carried out in antenatal clinics. In 138 cases, 42.8 per cent. of the patients suffered from constipation, 36.5 per cent. from flatulence and heartburn, 31.7 per cent. from severe varicose veins, and 52.38 per cent. from vomiting. All of the women received detailed teaching on hygiene—principally on clothing, diet and exercise; no medicines were given, except socalled domestic remedies, so as to maintain the purely educational character of the clinic and not to interfere with the general practitioner. Had the simple measures failed, the patient would have been referred to a physician, but this was not found necessary in a series of two hundred cases.

There is also a great need for research in antenatal physiology and pathology, in statistics on the conceptional rate, on intrauterine mortality, stillbirth rate, and also on intranatal and neonatal mortality; also analytical and experimental statistics on the effects of different toxins, x rays, etc., on the germ cell, or on the fetus during all the stages of its development. Such clinics especially endowed for such purposes are very costly and not all pregnant women would avail themselves of such an opportunity for various reasons, but an educational centre, planned along these lines, can be maintained almost as easily as an infant welfare station. It would also aid in collecting statistics on the effect on labor and lactation of different occupations and of the number and frequency of pregnancies, and of the relation between various menstrual disorders and fertility; it would also serve as a collecting centre, from which special cases could be referred to the larger and more fully equipped clinics.

Should the Kielland Forceps Be Used by the General Practitioner?—Klaus Hoffmann (*Zentralblatt für Gynäkologie,* May 20, 1922) states that the Kielland forceps gave very satisfactory results in a series of ninety-four cases. Young physicians, who never or only occasionally applied an obstetrical forceps, had no difficulty in using it and were enabled to spare the soft parts, which is a rare occurrence with the use of the ordinary obstetrical forceps. Cases that formerly offered considerable difficulties were delivered with ease by means of the Kielland forceps. The author recommends it as the only one to be used by the general practitioner and that the Naegele and axis traction forceps should be abandoned. It is needless to say that the physician must know the indications for its use as well as its manner of action. These should be taught to all medical students in the medical schools. Its great advantage is the fact that it can be applied to the biparietal diameter of the fetal head and that it is a protection to the maternal soft parts. Its advantages far outweigh its disadvantages.

Treatment Fracture of Femur.—C. E. Early (*American Journal of Surgery,* September, 1921) concludes that: fracture of the femur is a serious process, both in its immediate aspect and in its possibility of permanent impairment of function. The Whitman and Thomas splint methods bring almost perfect results if properly applied. The medical profession was slow to take them up but the great war and later experiences in industrial surgery proved their efficacy. Every case should be painstakingly watched. Daily inspection and frequent x ray examinations are as essential as the proper application of the method chosen for treatment. The mobility of the knee should be carefully guarded by free, passive, and active movements and by massage.

Control of Bleeding by Sodium Citrate.—Neuhof and Hirshfeld (*Annals of Surgery,* July, 1922) give the following summary in the use of sodium citrate: 1. The administration of sodium citrate intramuscularly, intravenously, or subcutaneously, results in prompt and pronounced shortening of coagulation and bleeding time. This is a hitherto unrecognized pharmacological action of the drug. 2. The shortened coagulation time is of two to three hours' duration with gradual return to the normal within twenty-four to forty-eight hours. 3. The sodium citrate curve occurs not only in individuals with normal coagulation and bleeding time, but also in those in whom there is pathological prolongation, notably in jaundice. 4. It does not occur in blood diseases characterized by blood platelet deficiency—hemophilia and purpura. These diseases appear to comprise the sole contraindication to the use of sodium citrate for the control of bleeding. 5. The dose for intramuscular administration of sodium citrate is nine grams for adults. A thirty per cent. solution is used, fifteen c. c. into each buttock, preceded by novocaine. The intramuscular method is free from danger, no untoward results having been noted in two hundred cases, and is therefore the method of choice. Internal as well as surgical bleeding, hemorrhage not only in normal individuals, but also in those with prolonged coagulation time are decisively controlled by sodium citrate injections in the great majority of cases. These are cases of oozing surfaces or hemorrhage from small vessels, for control of hemorrhage from large vessels cannot be expected with the dose of the drug at present employed. 7. The method offers as well a large sphere of usefulness as a prophylactic measure against oozing at operation, especially in cases in which much bleeding is anticipated.

Surgical Treatment of Chronic Ulcerous Colitis.—A. Krogius (*Finska Läkaresällskapets Handlingar,* July-August, 1922) reports a case of a forty-six year old female who had suffered eight years previously from pains in the abdomen and frequent bloody stools. She remained well for some time after treatment in a hospital. When the attacks recurred she was treated with enemas and typhlostomy. Again she remained well for a time. The last time that these attacks recurred, she could get no relief and showed no improvement from hospital treatment. The patient lost rapidly in weight and strength, and suffered from violent colicky pains, with increased peristalsis in the proximal half of the large intestine. The stools were frequent and showed blood and mucus. The mucous membrane of the rectum was of normal appearance. Implantation of the lower ileum in the pelvic colon was performed. The intestinal wall of the distal end of the transverse colon, descending colon and sigmoid showed marked inflammatory infiltration. The walls of the ascending colon and the greater part of the transverse colon were hypertrophic, but showed no signs of inflammatory changes. The pains disappeared after operation, the patient gained in weight, and the stools though still watery contained no more blood or mucus. Röntgen examination revealed no congestion of fecal contents in the colon. The author states that in his opinion colostomy is too often the operation of choice in chronic ulcerous colitis, when in many cases internal anastomosis would be the safest procedure.

Colloidal Benzoin Reaction of Cerebrospinal Fluid.—Fanny Warnock (*Journal of Laboratory and Clinical Medicine,* April, 1922) carried out the colloidal benzoin reaction as given by Guillain, Laroche and Lechelle, on all the spinal fluids received in the laboratories of the Michael Reese Hospital during five months. This study comprised eighty-seven cerebrospinal fluids, twenty-nine of which were diagnosed syphilitic, either clinically or from the laboratory standpoint, and fifty-eight of which were nonsyphilitic. Of the twenty-nine syphilitic fluids twelve precipitated in the syphilitic zone. Each of them continued beyond that range; of the fifty-eight nonsyphilitic fluids fifteen precipitated in the syphilitic zone. The following conclusions are drawn: Undoubtedly syphilitic cerebrospinal fluids do not regularly precipitate in any definite zone of dilutions. The benzoin reaction adds little in doubtful syphilitic cases. Tuberculous meningitic cerebrospinal fluids do not precipitate the colloidal benzoin in any definite range of dilutions. Many nonsyphilitic cerebrospinal fluids do precipitate the colloidal benzoin suspension, and even precipitate it in the socalled syphilitic zone.

Abstracts from Current Literature

Diaphragmatic Hernia.—Andreas Plenk (*Wiener klinische Wochenschrift,* April 13, 1922) reports a case in which a man, forty-four years old, always had a socalled delicate stomach and symptoms of gastric ulcer for twelve years. The pain radiated to the right shoulder and back from the epigastrium, and all his symptoms were aggravated by lying on his right side and by movement. A röntgenogram revealed a right sided eventration of the stomach with displacement of the stomach to the right. After a severe vomiting of blood and the beginning signs of perforative peritonitis he was operated on. The laparotomy revealed gastric contents in the peritoneal cavity and a fresh diffuse peritonitis; the stomach was displaced and dragged the duodenum steeply upward toward the esophageal foramen; gastric contents escaped from the left edge of the duodenum. The stomach could not be replaced because of numerous adhesions, which fixed both the pyloric region and the lesser peritoneum in abnormal positions. Because of his poor general condition only drainage toward the pleura and irrigation of the peritoneal cavity could be done. The necropsy showed the hernial site to be at the esophageal hiatus, slightly mesial and behind the tendinous centre of the diaphragm, just in front of the vertebral column. The stomach was almost entirely enclosed in a peritoneal hernial sac and was half turned to the right and posteriorly; the cardia was about seven cm. above the esophageal hiatus and the esophagus was just that much shortened. The peculiar features of this case are the absence of symptoms up to the thirty-second year of the patient's life, when the symptoms were chiefly due to an ulcer. The sites of pain in the epigastrium and right shoulder and the röntgenogram were significant clinically.

Cheyne-Stokes Respiration.—Hess and Rosenbaum (*Wiener klinische Wochenschrift,* June 15, 1922) state that respiration, circulation and muscular activity are primitive functions; the same applies to certain forms of muscular tremor. Cortical insufficiency may produce tremors just as do pathologic respiratory and blood pressure pictures. Periodic breathing and tremor may result from cold. The coincidence of variations in blood pressure and tremor has been noted in the literature.

The authors proceed from the assumption that the primitive functions of breathing, propulsion of blood and muscular activity rest upon a complicated collaboration of unequal and unequally affected centers. This theory is substantiated by a combination of all the remarkable pictures of Cheyne-Stokes respiration, tremor forms, and the Sigmund Mayer and Traube-Hering waves; only when the most peripheral and central neurons with their interposed connections are intact does normal work result. The most sensitive neurons are in the cortex. Owing to most varying conditions, these are irritated and pathologic respiratory, blood pressure and muscular movements result as a projection of the cortical decrease in function. In this way it is also possible to consider as a unit the associated phenomena of Cheyne-Stokes respiration (pupillary phenomena, motions of the eye, fibrillary twitchings, etc.). As soon as the pathological respiratory, blood pressure and tremor forms are more thoroughly correlated, they can be used as an indicator for the function of the cortex and may lead to extensive conclusions, similar to those drawn from the Babinski phenomenon. The cortex has a greater influence on the normal occurrence of respiratory and muscular movements and variations of blood pressure. In various ways which aim to detract attention during the respiratory pause, it is possible to produce slight respiratory motions. From this, as well as from the analysis of the tremor and of the blood pressure curve, the authors conclude that these phenomena are independent of the cerebral cortex, but that they are regulated by bulbar or spinal centers.

Mediastinal Displacement with Infiltrative Pulmonary Diseases in Infancy.—F. Thoenes (*Monatsschrift für Kinderheilkunde,* July, 1922) finds that a considerable displacement of the mediastinum not infrequently occurs toward the side of the diseased and infiltrated lung. This is to be attributed to the difference in pressure in the pleural spaces. This difference is the result of the deficient development of the elastic fibres in the infantile lung and the development of atalectasis, which is always present and results from the diminution in volume of the lung on the diseased side; this is not corrected even with expiration.

Backfire Fracture.—A. H. Bizarro (*Annals of Surgery,* July, 1922) states that the lower third of the radius and ulna is the commonest seat of backfire fracture, and the carpal bones the next common. The crack through the epiphyseal line of the radius is the commonest type of single bone lesion. The ulna styloid tip and radial epiphyseal line are the commonest types of double bone lesions. The scaphoid is the commonest carpal bone involved. In individuals under twenty years of age the diagnosis of ulna styloid fracture is more difficult owing to the common occurrence of irregularities of ossification. In twenty-five per cent. of the cases of the series the injury of the wrist was limited to the soft parts. The upper end of both radius and ulna are occasionally the seat of fracture. The age of the individual has no bearing on the fracture being at the epiphyseal line. The great bulk of these injuries is of the indirect type. The prognosis is usually good.

Shoulder Pain.—Z. Cope (*British Journal of Surgery,* October, 1922), in speaking of phrenic shoulder pain, concludes that pain of a referred nature is frequently felt on the top of the shoulder as a consequence of stimulation of the sensory terminals of the phrenic nerve in or near the diaphragm. The pain is felt in some part of the segmental areas corresponding to the third and fourth, and sometimes even the fifth cervical segments of the spinal cord. This referred pain is met with in many conditions which cause inflammation or irritation of the diaphragm or contiguous structures. There is an important localizing correspondence between the part of the diaphragm irritated and the position of the referred pain on the shoulder.

Miscellany.

Spinal Cord Compression Due to Circumscribed Serous Meningitis.—E. Sahlgren (*Hygeia,* August 16, 1922) reports the case of an elderly female with signs of hypertonia and arteriosclerosis, who, after an injury to her back, developed progressive paraparesis of both legs which was of a spastic nature in the beginning of the disease combined with paresthesia of both legs, but without root pains or disturbance of sensibility. Little by little symptoms also manifested themselves in the hip joints with bladder and rectal disturbances.

The clinical symptoms pointed to injury of the spinal cord. Patient recommended for operation; diagnosis: extramedullary, compressing tumor at the level of the eleventh vertebra. Laminectomy was performed. No tumor palpable. Incision of the dura revealed several osteoid patches in the arachnoid, the lowest of which at the level of the eleventh vertebra adhered to the dura, and on incision of the dura at this point the spinal fluid gushed out in greater amount and at increased pressure; the veins in this vicinity were much dilated. The osteoid patches were excised and the dura closed. Histological examination revealed no signs of inflammation or tumor formation. Immediately after operation the patient's condition seemed promising, but after about ten days the urine became scant and of high specific gravity, the heart grew weaker in spite of energetic stimulation, bronchopneumonia set in and the patient died on the thirteenth day after the operation. Autopsy showed renal and general sclerosis. Marked arteriosclerosis of the brain with moderate internal and external hydrocephalus. The cord showed no pathological changes microscopically and a section through the cord at the point where compression was suspected showed no histological change. The author believes it possible that the hydrocephalus and diffuse serous meningitis may have been caused by the trauma. A similar case is described by Bittorf (*Münch. Med. Wochenschr.,* 1916). Negative histological findings were reported also in similar cases. The symptoms were probably due to circulatory disturbances in the cord which left no permanent pathological anatomical change. We may therefore safely assume that in this case we were dealing with a case of circumscribed serous meningitis causing spinal cord compression, and also with a diffuse serous meningitis, both related to trauma.

Carcinoma and Pregnancy.—Friedrich Wolff (*Zentralblatt für Gynäkologie,* May 13, 1922) states that the opinions regarding the question whether pregnancy affects a uterine carcinoma favorably or unfavorably vary. In fourteen cases of carcinoma, which developed during pregnancy or the puerperium, eleven patients were twenty-five to forty years of age, which amounted to ten per cent. of all the cases of carcinoma seen in young persons (up to the fortieth year of life) during the same period of observation (one year). This finding does not support the view that pregnancy favors the development of carcinoma. In six cases, in which the carcinoma developed during pregnancy, only two were inoperable at the ages of forty-two and thirty-four. In the four operable cases, one showed a glandular recurrence after 2.25 years, three remained free from recurrences at the ages of twenty-nine, thirty-one, and thirty-nine years. Of the eight cases showing carcinoma immediately after the pregnancy, two were already inoperable at the ages of forty-three and thirty-six years; of six patients operated upon, one died immediately after the operation, three showed rapid recurrences at the ages of twenty-five, thirty-one, and thirty-nine years, and two remained cured at the ages of thirty-nine and forty-six years.

From these findings the author draws the conclusion that pregnancy has neither a favorable nor an unfavorable effect on carcinoma, and also that the age of the patient has no determinable influence upon the operability or danger of recurrence. He believes that there are benign carcinomas and also particularly atypical, rapidly progressive tumors, that the benign and malignant characters are biological variations of the tumor, depending upon their sources of origin and their blood supply, and that coincident circumstances, such as pregnancy, play only a subsidiary and possibly an undecisive part in the final outcome. Carcinoma is recognized more easily and promptly during pregnancy simply because pregnant women seek medical aid much earlier than nonpregnant women.

Cause of Hyperemesis Gravidarum.—Felix Ranzel (*Zentralblatt für Gynäkologie,* June 10, 1922) combats the theory that hyperemesis gravidarum is an expression of aversion and disgust and the reaction of the unwillingness of the woman to becoming pregnant. He substantiates his claim by the immediate cessation of the vomiting after indifferent remedies like the insertion of a pessary. This gainsays the psychogenic theory. Besides, necropsies occasionally show anatomical changes in the liver similar to phosphorus and fungus poisonings, in which cases toxic effects must be assumed as etiological factors.

On Diagnostic and Therapeutic Importance of Some Typical Tender Bone Points*

By RAFFAELE BASTIANELLI, M.D.,
Rome, Italy,
Professor of Clinical Surgery.

A great number of persons, especially women, complain of pain in various parts of the body, of which it is difficult to establish the seat and the nature, and consequently they are treated as suffering from nervousness, neuralgia, hysteria, or from material diseases of organs or parts of the body in the neighborhood of the pain, e. g., loose kidney, intestinal neuralgia, chronic appendicitis, arthritis, or periostitis.

For some years it has been an unlooked for privilege of mine to see a number of such patients, and, sometimes attracted by their report which evidently pointed to the seat of the pain, sometimes guided by the physical examination, I have been led to pay a great deal of attention to the bones as the possible location of the pain; and, as the treatment instituted, directed toward the affected bone, has been successful I have become fully persuaded that I was on the right track, and after years of observation I believe I can look at many different painful conditions from a general point of view which I venture to synthetize with the name of typical tender bone points, that is, of painful conditions associated with tenderness of some typical bone points. I prefer to give to these conditions the name of typical tender bone points to avoid entering into the essence of the thing and not to prejudice the question in any way, before a careful study may bring it to a satisfactory solution.

I call these points typical because they are constantly in the same spot, and so very well defined and accompanied by the same symptoms, more or less intense, that once you know them it is impossible to make a mistake. Some are infrequent and in various places—those are atypical. The patient rarely locates the pain at the proper spot, but generally indicates it in an indefinite way, so that it appears to come from a distant source. The patient seems to be unconscious of the bone as being the seat of the trouble. In some instances the pain is recognized and properly located by the patient. The common origin of the pain is in the apophysis, and precisely at the insertion of ligaments or capsules or fibrous muscular attachments, hence the names of apophysalgia, epicondylalgia, or epicondylitis—names which are better avoided since we do not know anything definite, and since the same painful points are to be found on flat bones like the ribs or their cartilages, the scapula, the pelvis. It is typical that the tender spot is extremely well circumscribed so that the pain can be found with the edge of the nail. By pressure outside of this small area no pain is felt. The moment you reach the vital point the pain is vividly expressed, and in many instances the patient tells you clearly that the source has been reached. From those points the pain radiates to a distance, sometimes following paths that are not definitely traceable along the nerve trunks or branches. Sometimes the pain is felt more in the immediate vicinity, sometimes it is accentuated during certain movements. The pain may be constant but variable, or at intervals, or have a neuralgic character if it comes by attacks.

The initial symptoms are not frequently acute or sudden and continuous, but more obscure, indefinite, insidiously growing with time. The pain is felt as dull, boring, tearing and spreading and commonly worse at night. It may prevent or disturb sleep and disable a limb or completely prevent work. The course of the disease is variable, usually obstinate, and sometimes with free periods. It often lasts for years. It is easy to conceive that if such a painful spot bears a relation to a neighboring structure, like a joint, for instance, the pain may be attributed to a disease of the joint; or if near tendons or nerves, to them. If the bone point has not been looked for, and if the relation is such as to make one think of an abdominal organ, say the kidney or the appendix, the pain will be certainly attributed to it. Following that, I believe it logical to group the painful points into those which may give reason for con-

Copyright, 1923, by A. R. Elliott Publishing Company.

fusion with diseases of joints, nerves, and tendons, and those which may be confused with visceral diseases.

The first time I saw such a case was twelve years ago. A woman of middle age complained of intense pain in the right shoulder, anteriorly, spreading to the scapula and arm, tearing and pulsating at times, which had appeared in a rather acute way three months before, growing with time, being intense in the night, and preventing sleep and some movements of the arm, so that she preferred to keep it immovable. She had been treated for arthritis of the shoulder for a long time without success, and it was finally decided that she was suffering from chronic rheumatic arthritis. The examination showed that the shape of the shoulder was not changed; the right deltoid was slightly, if any, less in bulk and in power of contraction than the left, and pressing along a horizontal line under the acromion, that is, on the socalled interarticular line and along the bicipital groove, there was no pain at all, but the pain was intense and unbearable by pressing deeply on a point on the anterior border of the deltoid, close to the pectoral deltoid interstice, under and a little outside of the coracoid process. The point was constant and could be limited exactly to a small area, outside of which no pain at all was experienced. The active movements were possible but the outward and backward were made cautiously and limited. By impressing passive movements to the joint, holding down the shoulder, and sustaining the elbow in such a way that no stretch at all was put on muscles and ligaments, the movements were all possible and painless, but it was difficult to force the outward and backward rotation.

The radiograph was negative. By putting the head of a metal probe on the spot it could be seen under x rays that it corresponded very nearly to the smaller tuberosity. I was impressed especially by the disproportion between the severity of the pain and the possibility of the movements, by the absence of swelling and of muscular wasting, and then I began to pay attention to the only fact discovered—the pain at that point. With the help of the experience gained in other similar cases, of x ray pictures, and of anatomical preparations, I have determined that the point is situated just outside the capsular insertion, close to the limit between the small tuberosity and the anatomical neck, where are attached the joint capsule and the inferior fibres of the coracohumeral ligament. It is quite well known, and has been for a long time, that in the course of shoulder arthritis there is a tender point under and outside the coracoid. It is given also as a differential symptom of such a disease, and interpreted as corresponding to the convexity of the head of the humerus (Duplay, Rochard, Demoulin). But this is not accessible unless the arm is in a forced outward rotation; instead, this maneuvre is not necessary to find the painful point of which I am speaking. The same authors say that in the arthritides pain is to be elicited in the deltoid pectoral interstice, and, as they do not speak on that occasion of any maneuvre of rotation, certainly the painful area is that which I believed it to be, that is, not the articular portion of the head but that limited area near the anatomical neck.

The same painful point is described as being present in a variety of arthritides, socalled traumatic, in which, notwithstanding the great authority of Sir Robert Jones, I believe the traumatic element has very little to do, unless we call traumatism the use of the joint, but certainly it may be during an exaggerated or forced movement that the pain is first experienced as being the occasional cause of putting into evidence the initial stage of the disease due to some other influences. But laying aside that discussion, I will recall also that the same painful point is described in the socalled subcoracoid bursitis. This bursa is, in Europe, disregarded as being too small to give any source of trouble (DeQuervain) but recently Goldthwaite and Codman have so very interestingly attracted attention to it that I think it would be unfair to such authors not to remember it. I have had no experience with this disease, neither have I heard it mentioned anywhere in our country, but for my purpose it is enough to ask why the same painful point is once attributed to the intraarticular portion of the head of the humerus, why another time to the inflamed bursa, or to a deep part without precise location? Is it not simple to accept my assertion that it is always the same area which is the seat of pain, especially when you can demonstrate it anatomically and confirm it clinically by the success of treatment?

So much for the diagnosis of its location. But as a symptom of disease, what is its value? It is of secondary importance in the diagnosis of arthritis, as there are far better signs, but it is of greater importance in establishing a new entity, the one of the painful bone point, as existing by itself, giving origin to radiating pains and to be differentiated from other diseases.

In case of the existence of this point on the humerus (which I will call humeral superior point) the differential diagnosis is first concerned with the arthritides, as the location of pain and the impairment of some movements, commonly bring us to such a diagnosis. If one pays attention to the shape of the shoulder, to the condition of the muscles, to the possibility of impressing any movement to the arm when capsule and ligaments are held relaxed, except the outward backward rotation as being the one which stretches such structures, and the presence of only this painful spot, the diagnosis is easily accomplished. I have seen many instances of incorrect diagnosis going even to that of tuberculosis. Many socalled homalgias, arthralgias or neuralgias of the joint, deltoid and humerus are due to the same cause. The same pain, when it is running in the arm with indefinite location along the nerves, is called brachialgia. This is especially true when the humeral superior point is associated with points on the fourth and fifth ribs posteriorly, between the medial margin of the scapula and the spinal column, and also with scapular points, on its spine medially, or on the medial angle. When the physical examination, including the x rays, has excluded the many lesions which may give rise to the brachialgia and when these bony points are distinctly found, there is no doubt that they are the source of pain, as it is proved by the result of the appropriate treatment.

The socalled osteoperiosteal neuralgia is definitely different for it consists in pain in the shaft of the long bones, usually in the upper part of the humerus under the surgical neck, occurring mostly during the night and without any tender spots, as I could see, in two typical cases.

The styloid process of the radius is a common painful point. The patients, usually women, do not locate the pain in the bone, but vaguely near that area. Usually they complain of pain during ulnar and dorsal flexion of the hand, in abducting the thumb, in grasping and in raising a weight. The pain radiates along the thumb, the radial, dorsal side of the hand and of the forearm, even in the arm, and some persons are incapable of doing any work, even playing the piano or sewing. The location of the pain is definitely on a limited point just at the tip of the styloid, and nowhere else. There is no change of shape in the wrist and the movements can all be accomplished if not forcibly done. I have seen cases treated as arthritis, with immobilization, and with no result, though rest improves the condition greatly. The differential diagnosis is easily made by paying attention to the previously described signs and especially to the disproportion between the pain, severe at times, and the possibility of movements, and to the localized small spot of tenderness.

Periostitis, osteitis, neuralgia of the joint, inflammation of the tendon sheaths have also been common diagnoses. These false diagnoses are easy to avoid by remembering the peculiarity of the painful bone spot.

De Quervain some years ago described a peculiar disease in the wrist called tendovaginitis stenosans, and Keppler and others seem to have confirmed it. Permit me to remind you that the author described it as a relative narrowing of the tendon sheath of the extensor brevis and abductor longus pollicis, and not an inflammation, because he could not detect any sign of it but only a thickening of the sheath. It appears mostly in women and the pain described is exactly the same as I have told you for the painful point. Clinically he found a pressure pain and usually a certain thickening corresponding to said sheath. In laying it bare one can see the tendons choked, as it were, and cutting the tendon with a tenotomy knife, subcutaneously, the patient was cured forever. I have never seen such a thing and I do not dare to doubt it, but I may be allowed to think that the tender spot may have something to do with it, if not always, at least sometimes. I ask you to think of the similarity of the symptoms, of the inexact location of the pain as given by De Quervain, of the frequence in women, as in my cases, notwithstanding that they work less hard with their hands than men. Then I ask you to think of that strange pathological entity of a narrowing of a tendon sheath, a disease of which we have no other example in the body.

After having expressed these ideas I may briefly mention the socalled epicondylitis, epicondylalgia, which has been known for a long time and variously interpreted, as due to laceration or stretching of the external ligament of the elbow, to a stretching of the radiohumeral capsule, to a neuralgia, to an inflammation of periosteum or a bursa, and so forth. I believe that the exact localization of the pain is in a limited spot of the epicondyle just at its anterior point, in view of the absence of any material sign of lesion in the joint or in the muscles. The sometimes spontaneous onset indicates an essentially tender bony point, and I will dismiss this as well acceptable, avoiding the discussion of it as probably too tedious. Other painful points in the upper extremity may be found on the styloid process of the ulna, on the bases of the metacarpal bones first and second, on the os pysiformis.

In the lower extremity the bony spot most interesting is the one situated on the internal tibial condyle, anteriorly, about midway between the middle and the internal line of the knee, and exactly on the infraglenoid margin. This point is just outside the insertion of the capsule, probably where are attached fibres proceeding from the internal patellar retinaculum and passing down to the tuberosity of the tibia. This point has nothing to do with the one often found on the insertion of the internal lateral ligament. The pain spreads on the internal side of the knee and is likely to become worse during exertion so as to prevent free movement and to cause vague alarm. I have seen many patients suffering from that pain and treated for rheumatism, for arthritis of the knee, tuberculosis of the internal condyle, and other conditions. But the physical examination showed the integrity of the joint, the possibility of movement being complete when the capsule and ligament were not put on the stretch. The radiograph showed a normal bone and the pressure showed only a limited painful area. This point I wish to call the tibial superior. I need not dwell on similar pain, well known, on the attachment of the lateral ligament of the knee occurring in true diseases of the joint, which, like the one mentioned, may be present in the true arthritides like the humeral superior point in the shoulder joint inflammation. But those may also be independent and generally the error is made that when one finds pain either on the tibial point or on the ligamentary insertions, one thinks of the joint and not of the bony spots as being the seat of the disease.

I wish also to mention the painful spots, on the head of the fibula, on the external tibial and femoral condyle, on the margin of the patella, on the apex of the malleoli, on the internal side of the navicular bone, on the dorsal aspect of the base of the second and third metatarsal bones, and on the plantar surface of the head of the fourth and third metatarsals, on the posterior and on the inferior surface of the calcaneus. I will not venture to say that many of the socalled achillodynias, podalgias, metatarsalgias, and especially the Morton painful foot, and the tarsalgia of some young people in which the navicular bone is extremely tender, are due to some painful bony spots, but I am sure there is ample room for an exact differential diagnosis and that in many cases it is only the tender bony spot which is the cause of the suffering, as is amply proved by the result of the local treatment.

I have already spoken of the ribs as the seat of pain which is located on the fourth and fifth posteriorly between the scapula and the vertebral column and associated with tender scapular spots and with symptoms of indefinite brachialgia. The point situated on the inferior costal border is also important. When on the right side and corresponding to about the place of the socalled cystic point, this gives rise to the diagnosis of biliary colic, of hepatalgia, and also to the removal of the gallbladder, without any cessation of the pain, which was promptly ended by the local treatment. The painful tip of the eleventh and twelfth rib also gives rise to many diagnostic errors.

The spinal column has been long known as the seat of pain not in relation with material lesions. I need only to recall the hyperesthetic spine of neurotic people, of hysterical women, in which the pain is described variously by different authors. As, for instance, Gowers says that pain is felt through a considerable vertical extent of the spine, and is especially intense in certain spots, usually in more than one. The dorsal region is the most common seat, next the lower cervical, and least frequently the lumbar region, sometimes on one side of the spine close to it. Oppenheim speaks in about the same way, pointing to the hyperesthesia of the skin above the painful spines. He notes also that there are pains deeply located, apparently on the muscles, in the fascia, or on the periosteum. There are certainly true hysterical patients having such pains, but there are also others who have tender spots located exactly on the tip of one spine, without skin hyperesthesia, from which the suffering begins and spreads in various ways. To dispose of these people as neurotic seems to me excessive. The exact study of the matter and the result of treatment have persuaded me of the existence of such tender bony spots as the only cause of the pain, and independent upon hysteria.

The seventh cervical, or prominent, spine has given rise to errors. In two girls having that spine more pronounced and intensely painful the diagnosis was tuberculosis of the spine and the plaster of Paris jacket was carried vainly for a long time. When appropriate treatment was instituted they were quickly cured. Chipault has described such pain in cases of Pott's disease and not in relation to the carious process. This socalled apophysalgia is of great importance for we may be easily brought to a wrong conclusion. I believe that pressure tenderness on the spine is not at all characteristic of Pott's disease —but only the pain produced by trying to displace the spine from side to side. I believe that pain on the tip of one or more spines is not due to caries, but to this special painful condition of the bone, as it is proved by the local treatment (Chipault). We have far better signs than this for such a diagnosis, and now the x rays are of such help that it seems easy to reach a right conclusion. When an essential spinous tender spot is present there is always free mobility of the column and no contraction of the muscles, if the movements are made to avoid a sudden stretching of the ligaments. Besides, the limited, precisely definite area of pain is for me of deciding importance. The point apophysaire described by Trousseau and denied by others as existing in the intercostal neuralgias, the painful spinal points described in the course of liver and gallbladder disease by Charert, Vidal, Mackenzie and others, certainly deserve attention, but there is the possibility of confusion with the true bony tender points.

The sacral region and the posterior iliac spine close to the sacroiliac joint, also often the seat of limited pain, which may radiate in the buttocks, along the thigh, and may simulate various diseases, like sciatic neuralgia, sacroiliac joint stretching, lumbago, backache of indefinite location and origin, and so on. In every case of such indefinite pain the accurate search for a tender bony spot may at once make the diagnosis and the treatment easy. What a place, according to such ideas, the socalled coccygodynia takes is easy to understand. In such cases there is always a limited tender spot, generally at the very tip of the coccyx, from which the pain radiates, as you well know. The painful spot located on the tip of the lateral process of the third lumbar vertebra has to be considered with more detail. So far as I know such a pain has never been described. I know only of Nicoladoni having pointed to the pain present on the fourth lateral lumbar process during lumbago. This is true, and often there is pain on both sides, and even on the second and third processes, in those cases. But the one I speak of is independent of any other disease and such that only the physical examination does reveal it. The patient generally locates his pain vaguely in the back and complains of pain spreading in an indefinite form along the waist, running anteriorly to the iliac fossa. Women are mostly affected by it, and rarely is a cause to be found. In some the onset is sudden and acute. A lady of fifty years, unmarried, seen by me in 1914, reported that she had been suffering for four years. One day while running up hill she was seized by pain in the right loin so severe as to almost make her faint. The pain continued severe for five days, then subsided but never stopped, and at that time was growing more intense, at times less, but especially in bending and during exertion it was more severe. She was a thin, pale woman, and nothing could be detected but a painful spot on the tip of the third lumbar lateral apophysis. With local treatment she was quickly cured. This is an exceptional occurrence and points more to a traumatic origin, but in the majority of cases the trauma is not to be found, though sometimes there is a rheumatic influence.

The characteristic part of such an affection is that the patient is unaware of the bone point and refers the pain to the posterior side, to the flank, and to the abdominal inferior quadrant, with a more anterior tender point vaguely located about the middle of the iliac fossa; the pain may be in the form of attacks, and during exertion or even in the night. Recently I saw a strong peasant coming back from America because he could no longer do heavy shovel and pickaxe work on account of pain arising in the right loin. He had been vainly treated in many ways. He reported that he had suffered from it for many years and he could not remember the cause of it. There was only pain in that peculiar point of the third lateral lumbar process, which when pressed was at once recognized by him as his particular pain, and he was cured by the local treatment.

Certainly the most common sufferers are women, thin, generally neurotic, others fat and apparently normal, and it is possible perhaps to attribute such a pain in some cases to efforts, in some to rheumatic influences, but generally it appears as idiopathic. During the examination of these patients, which is best made in the lateral posture, often one may find another painful point anteriorly and deep by pressing against the lateral side of the body of the fourth lumbar vertebra. This is an exquisite pain, and sometimes it is to be found on both sides. Let us call it anterior lumbar pain in opposition to the posterior one described. The fourth vertebral body is the most frequently affected, but sometimes the third.

The posterior pain generally gives rise to the diagnosis of backache, or of lumboabdominal neuralgia, or of loose kidney, or nephralgia, or neurosis, and I have seen many women operated upon by fixation of the kidney and not cured. Certainly I have seen the pain present in rare cases of true kidney disease, but the physical examination, the study of the urine, ureteral catheterization, and x ray examination clear up the diagnosis, and then when all investigations are negative and the painful spot is present one may be sure of being on the right path.

It is more difficult to get rid of the errors arising from the pain of the fourth lumbar body, for when we enter into the great field of abdominal pain and consider the many possibilities we feel really embarrassed in many instances to reach a conclusion. Generally in those cases the diagnosis is made of chronic appendicitis, of painful cecum, of enteralgia, or simply iliac algia, which name is very well selected to cover our ignorance. I shall not dare to trouble you with the vexed question of the chronic appendicitis and of the painful abdominal spots in relation to it. If one would map out on a scheme of the human abdomen all the painful points described in connection with appendicitis, or of enteralgia, or of pain of the celiac plexus, of the aorta, of the iliac arteries, and other organs, one would get a map like that of a starlight sky, but these stars unfortunately do not give any light to the man who wishes and needs a clear sight in such profound darkness.

Those points do not work, do not help, but in a secondary way and it would be better not to be led by them alone in diagnosis, and I am persuaded that many of them have been worked out from preexisting ideas and artificially. Dr. Morris, of this city, has drawn attention to a painful point located deeply at one and a half inches from the umbilicus on the spinal umbilical line, on the right side, and due to irritation of sympathetic ganglions during the course of what he called the protective appendicitis, or the syncongestive appendicitis. If the pain were bilateral he thought it was a sure sign of pelvic affection, if only on the right, a sign of appendicular trouble. This pain really exists, but it is a pain located on the bone, and it is just the one pain I have spoken of. You need not search for it at one and a half inches to the right of the umbilicus. It generally happens that, when examining a patient for tenderness in the iliac fossa, as soon as the hand begins to go deeper and the finger unconsciously to stretch a little way medially, they meet the lateral side of the fourth lumbar body, press it and elicit the pain, which if not accurately studied, is at once pronounced to belong to the appendix. I do not give to this pain any importance as being positive for the diagnosis of appendicitis. On the contrary, I am persuaded that it has nothing to do with it, even if inflammation of the appendix should eventually be present. Then it would be only a coincidence. This pain is found almost exclusively in women having even no pelvic ailment, more to the right, and the question is open whether it is a hyperesthesia of sympathetic fibres made evident by the pressure against the lumbar body, or whether it is an exquisite hyperesthesia of the periosteal surface of it, as are all the other bony points already described.

The anatomical and etiological foundations of such a lesion are not definite. It occurs commonly without any anatomical lesion, and the macroscopical investigation of fragments removed by operation have not yielded appreciable results. Apparently there is not a common osteoperiostitis, neither a socalled angioneurotic periostitis for we never see sudden infiltration appear and disappear. Minute studies on the sensitive termination of nervous filaments in the ligamentous attachments to the bone in those spots have never been made.

Do we know anything better of sciatica, and the other neuralgias? Is it possible that the socalled traumatic, rheumatic, gouty, neurotic elements have some rôle in the production of this lesion? Recently I have seen a man with epicondylic tender points, bilateral, of long standing, have a sudden exacerbation and develop swelling of the left wrist joint, in the absence of any demonstrable affection, which was improving under antigout treatment. Is it possible that indefinite infective causes, or, as Adams called it, subinfection, could produce it, as we believe are producing the socalled chronic rheumatic affections and fibrositis? These are open questions.

But one thing is sure, that there is a local treatment most effective, that is the injection of ten to twenty minims of carbolic acid in the strength of three or five to one hundred, injected deeply on the very bone exactly in the painful point. The injection must be repeated four to five times at different intervals according to the reaction. In the chronic cases, especially of the superior humeral, superior tibial, posterior lumbar, and rib and scapula points, the results have been extraordinary; less in the epicondyle and styloid pain and in the coccygodynia, perhaps because it is more difficult to inject them well. In the acute form I generally wait, but at the request of busy patients I have sometimes performed the injection with variable results, as the reaction following in those cases is more severe and the disease for the time being becomes worse. It has been a source of satisfaction for me to read in Llewellyn and Jones's book on fibrositis that Wilfred Harris has cured brachialgias by injecting alcohol on tender points accurately localized on the scapula and on the ribs. Certainly Dr. Harris was in the presence of such cases as I have described, and to find that two independent persons move along the same way is a reason to believe that it is the right way. At any rate, the many therapeutic results obtained by me and by others in Rome, with only such a local treatment are the best proof that these painful bone spots are a real independent entity.

Morgagni wrote that the more frequent a disease, the more essential it is that its phenomena should be carefully investigated and, if possible, linked up with some structural changes in the body textures. Unfortunately I have been very far from accomplishing such an ideal, nor does it seem possible now. What I have presented is a small part of a large field, that of pain, a study most difficult and complex.

I have endeavored to submit this small part of it for your consideration, presenting it from a general comprehensive point of view, as I believe it has not been done before.

A New Method of Treatment of Irreducible, Acquired or Congenital Hip Dislocations

By ADOLF LORENZ, M.D.,
Vienna.

Although having quite a different etiology, the following conditions, luxations, pseudarthrosis colli femoris, coxa vara luxans, anatomically have something in common. From this anatomical similarity there arises a nearly equal disturbance of function in these otherwise different conditions. Similar functional disturbance suggests similar, or rather identical, treatment.

What is it that these different conditions have in common anatomically? Evidently a loosened connection of the upper end of the femur with the pelvis. In cases of inveterate luxations of whatever character, this connection is effected by the distended capsular tube. The same is the case in ununited fractures of the neck of the femur, though the pseudarthrotic fibrous tissue between the fragments of the neck more or less adds to the tightness of the loosened connection of the pelvis with the upper end of the femur.

This relatively increased tightness of connection in the case of ununited fracture of the neck of the femur accounts for the fact that even in very loose pseudarthroses the dislocation upward of the peripheral fragment never will reach degrees usually seen in inveterate luxations.

The ligamentum teres does not count in either case: in the case of inveterate luxation it has been destroyed, and in the case of pseudarthrosis it is not put to strain.

The inveterate congenital luxation means displacement upward of the entire upper end of the femur, while pseudarthrosis colli femoris represents displacement upward of the upper end of the femur, minus the head which is retained in the acetabulum.

In cases of socalled pathological luxation of the hip joint, when the head of the femur has been destroyed either by a tuberculous or osteomyelitic process, the similarity to pseudarthrosis is still greater. In both cases the upper end of the femur minus the head is luxated upward, the only difference being that the displacement upward in pseudarthrosis of the neck is less, and that the head is left in the socket.

In cases of severe coxa vara, when the neck of the femur is depressed under the horizontal line forming an acute angle with the shaft of the femur, the head of the femur necessarily develops a tendency to subluxation; therefore the name, coxa vara luxans. Also, in these cases, though in a lesser degree, the connection of the pelvis with the upper end of the femur is impaired. The functional disturbances caused by such similar anatomical conditions consequently are nearly the same.

The pelvis in all these cases has lost the direct bony support of the femur; it is no longer propped by the bony pillar of the femur, but is merely suspended at its upper parts by soft and yielding tissues, the capsule and the pelvitrochanteric muscles. These soft parts, subject to undue strain especially in adults of heavier weight, become painful.

I used to call these pains the tearing or distention pains (*Zerrungs Schmerzen*). Such pains at times totally disable the patient. At any rate, they considerably interfere with the endurance in walking.

The limping of such patients is due not only to the deficient bony support of the pelvis, but also to the fact that the power of the pelvitrochanteric muscles is deficient, for by the shortened distance of their points of insertion they have become too long, have lost their normal leverage, and beside are weakened from disuse. They are no longer able to hold the pelvis in the horizontal line when the diseased leg has to support the trunk. The contralateral side of the pelvis drops until the lateral aspect of the tuber ischii reaches contact with the inner aspect of the upper femur. Though this contact is not a bony one, the cushion of the soft parts between the bones steadies the pelvis and prevents its further dropping down. I mention this fact intentionally, because a therapeutic measure of which I shall speak later on has been founded upon it.

The lateral dropping of the pelvis at each step accounts for the adduction contraction met with in all these cases. Habitual adduction induces flexion contraction, which furthermore is favored by the fact that the dislocation of the upper end of the femur takes place not only in an upward but also in a backward direction.

The concomitant outward rotation of the thigh is of no practical—rather of a theoretical—importance. It is a sign of the loosened connection of the pelvis and femur, which allows the thigh to follow its own weight.

I must lay stress on the fact, which has always been overlooked, that the conditions named above, comprising much of the pathology of the hip joint, always are complicated by flexion adduction contraction of the thigh. (I omit outward rotation because it is of less importance.) Nearly all pathological conditions of the hip joint, with few exceptions of no interest in the present matter, offer at the end of the course of the underlying disease the same contractions of adduction and flexion. Therefore I am accustomed to denominate flexion adduction as the socalled typical contraction of the functionally deficient hip joint.

This fact offers a point of attack of which I have made use especially in cases of pseudarthrosis colli femoris and inveterate luxations. It stands to reason that merely by correction of this concomitant contraction some good can be derived. But such correction alone means only symptomatic treatment, because it does not solve the question of the pathological suspension of the trunk and the pelvis on the femur.

Since the day when I had to recognize the fact that there are, in many cases, certain insurmountable limits to bloodless reduction of the congenitally luxated hip joint, it has been a pet idea of mine to cause the femur to make a side way, or detour, to reach the acetabulum, instead of passing by, when it had become impossible to reduce the head into the socket. Then the elastic and yielding suspension of the pelvis, i. e., of the trunk, at the upper end of the femur, would be changed into a bony support of the pelvis by the femur, that is, by that part of the femur which is opposite the acetabulum.

To be able to make this side way, the respective part of the femur first must be isolated by a cut of the bone at the level of the socket. Then the upper end of the lower fragment would represent, as it were, a newly created artificial head, to be placed in the socket instead of the real but irreducible head; this latter would remain where it was; the lower end of the upper fragment would be united with the lower fragment by bony tissue. Thus the upper end of the femur would be transformed into a fork with two unequal teeth or prongs. This would be effected by an osteotomy of the upper end of the femur and by the displacement of the lower fragment inward against the capsule covered socket, while the lower end of the upper fragment by adduction would be brought into contact with the upper end of the distal fragment below its insertion into the socket.

The long blunt tooth, or prong, is represented by the head and the great trochanter; the short but pointed tooth by the upper end of the shaft of the femur. Therefore, I call the procedure bifurcation of the upper end of the femur. This nomenclature was chosen because of its shortness as well as descriptive significance.

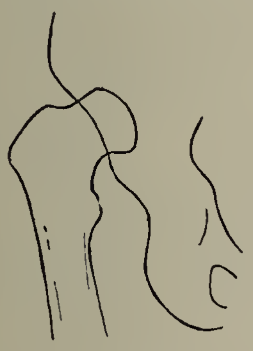

Fig. 1a.—Irreducible hip luxation.

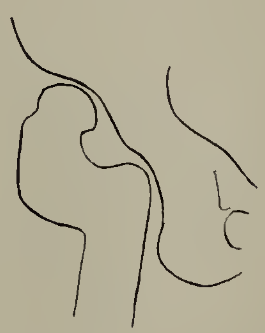

Fig. 1b.—A diagrammatic sketch embodying the idea of the operation, which means deflection into the acetabulum of that part of the femur which is at a level with the socket. As it were, the femur makes a side way to reach the socket, instead of passing by it at a distance.

To characterize more clearly the operative procedure I could have preferred the title: Reduction into the acetabulum of that section of the femur which is at a level with the middle of the socket. This would have been a description rather than a name for the procedure.

But using the name bifurcation, it must be borne in mind that the characteristic feature of the process is reposition, or reduction of a newly created head into the socket. I must emphasize this fact, because I expect that—propagators of subtrochanteric osteotomy in cases of irreducible hip dislocation will say that there is nothing new about my bifurcation.

As far as the osteotomy is concerned (although there are quite remarkable peculiarities in bifurcating osteotomy) that may be true. But osteotomy in bifurcation means nothing but a preparatory act to the reposition of an artificially created head.

Simple subtrochanteric osteotomy as recommended by Kirmisson means nothing else than correction of flexion adduction contraction of the thigh. I have always objected to this method because the same, or an even better effect, can be brought about by my bloodless procedure of inversion, as I will explain later on.

Beside correction of the contraction, v. Baeyer, of Wurzburg, had still another aim in mind when he proposed subtrochanteric osteotomy in these cases. He advocates strong abduction of the lower fragment. When, after bony union of the fragments, the distal one is put in an indifferent position, the upper end of the proximal fragment, i. e., the trochanter major—must become more removed from the outer aspect of the iliac bone. Consequently the pelvitrochanteric muscles become stretched, their points of insertion become further separated and their leverage improved. But this does not mean reposition of an artificially created head of the femur.

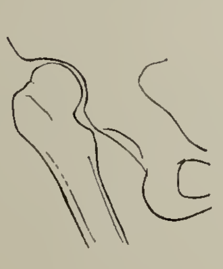

Fig. 2a.—An irreducible hip dislocation.

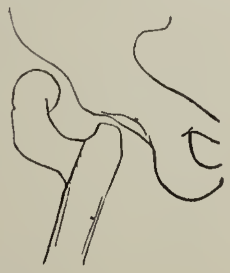

Fig. 2b.—(An outlined x ray picture) shows how the theoretically construed deflexion of the femur looks in reality a short time after the bifurcation operation. The upper end of the distal fragment—after oblique osteotomy—has been reduced into, or rather on the socket, by abduction and other maneuvres; the lower end of the proximal fragment, by adduction has been brought in contact with the distal fragment underneath the new artificial head, and will be united at this place by bony tissue. The upper end of the femur suggests a fork with a blunt, long prong (head and trochanter major); and the short, pointed prong (shaft of the femur) on the acetabulum.

A third subtrochanteric osteotomy, a little lower down, at about the level of the tuber ischii, has been recommended by Schanz, of Dresden, quite recently. By choosing this place in correcting adduction and flexion into abduction and extension he has in mind the elimination of the Trendelenburg-Lorenz[1] symptom by keeping the upper part of the femur in strongest adduction to the pelvis while correction of this position is performed at a lower level opposite the os ischii. This idea has a sound foundation, and I dare say that I considered its possible efficiency many years ago on my way to bifurcation. But this

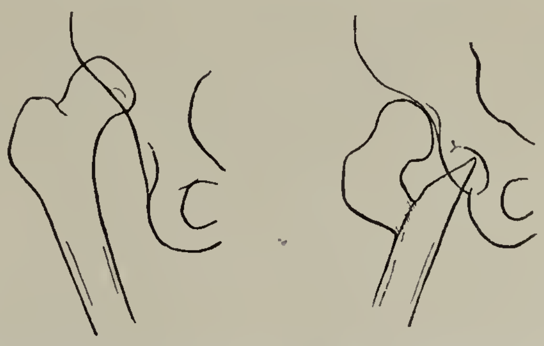

Fig. 3.—The same explanation (Fig. 2b.) holds true. The left sketch represents an irreducible traumatic hip dislocation. The outlined x ray picture on the right side shows the anatomical result of the bifurcation.

---

[1] Some pupils of mine added my name to that of Trendelenburg because this symptom coincidentally and independently had been described in my book on congenital dislocation.

Schanz osteotomy, also, is far from sharing any feature with bifurcation.

I may rightly state, then, that bifurcation is a completely new operation of a quite distinct character, and this character is reposition—surely not of an irreducible head, but of a substitute head, created by the preparatory act of osteotomy.

I have often met with difficulties in making the idea of the bifurcation operation quite clear to many who have asked me about it. In order clearly to differentiate bifurcation from simple osteotomy, and to explain the idea of the operation, I have made diagrams, which are outlined x ray pictures.

After having explained the idea of the bifurcation operation, I hasten to add that I am by no means of the opinion that the operation should be performed indiscriminately in any of the above described conditions. On the contrary, we must carefully select the cases. The principal inducements to operate upon a case are inability to walk or unendurable pains. I would not advise the operation for cosmetic considerations, although the cosmetic results of the operation have been surprisingly good. It must not be forgotten that the method is a palliative one and that there are some drawbacks.

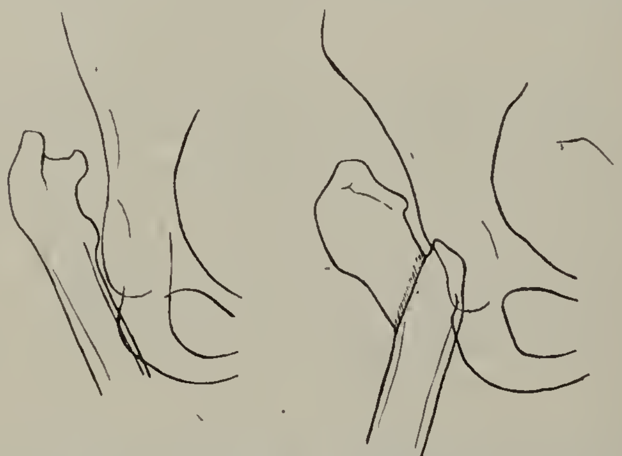

FIG. 4.—Shows at the left side the outlined x ray picture of a pathological osteomyelitic luxation. The upper end of the femur, the head being destroyed, looks like a broomstick. The sketch on the right side shows the bifurcation.

In the first place, the operation entails some shortening, which, however, can be equalized easily by the tilting of the pelvis at the side operated upon. In the end the high heel, which is necessary after the operation, as a rule is not higher—often lower—than before the operation. Stress must be laid on the fact that not the shortening but the elastic suspension of the body on the upper end of the femur is the sourse of the troubles of the patient.

To a certain extent mobility of the hip joint, especially flexion, is impaired, because the upper end of the shaft of the femur (the new head) acts as a brake when sliding on the anterior wall of the capsule. In spite of this limitation of movement, neither walking nor sitting is seriously interfered with. In many cases the flexion reaches nearly 90°. It seems that in the course of time flexion increases. This is due, probably, to the formation of a sort of sliding, smooth surface between the capsule and the new head. Also it is to be expected that by functional use the newly created head will lose its pointedness, becoming rounded by increase of its diameter.

It was an important question whether the pressure of the pointed new head on the capsule or on the periosteum would not cause pains. This may be so at the beginning, but my fears were dispersed by experience. Without being asked, many patients declared that while treading on the diseased leg they no longer felt the well known and disagreeable sliding up and down of the hip bone (trochanter major) but felt firmly supported by the thigh, and that without any pain.

Furthermore, it must be borne in mind that the operation does not aim at a cosmetic result—at least not in the first line. We do not operate upon the patient because he limps, but because we want to do away with his pains when walking, because we want to enable him to walk with endurance, while the cosmetic question is of secondary importance. I say so in spite of the fact that in many of my cases the cosmetic result has been excellent also. I think that at any rate the operation should be done in cases which are incurable, being beyond the means of any other therapeutic measure. This is the case with pathological (tuberculous or osteomyelitic) luxations of the hip joint and of coxa vara luxans. In these cases we have no other means of treatment but the operation. In cases of irreducible, refractory congenital luxations and in cases of pseudarthrosis colli femoris, bifurcation should be the last resource.

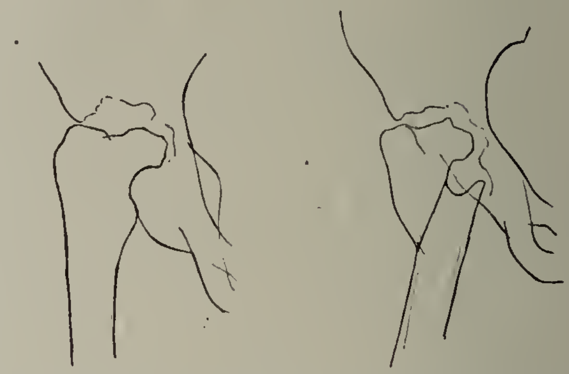

FIG. 5.—Left, shows a pathological subluxation of tuberculous origin. A minute head stands in an enlarged socket (function became painful after even light strains). On the left side, by the bifurcation, the pelvis is propped at the lower rim of the socket. Bifurcation of the upper end of the femur in cases of pseudarthrosis colli femoris offers a somewhat different picture.

Although in possession of bifurcation, I have not given up my bloodless methods, resorting frequently to what I have called "Inversion," especially in bilateral inveterate luxations with severe contractions, and in pseudarthrosis colli femoris complicated by strongly developed flexion adduction contraction of the functionally defective hip joint.

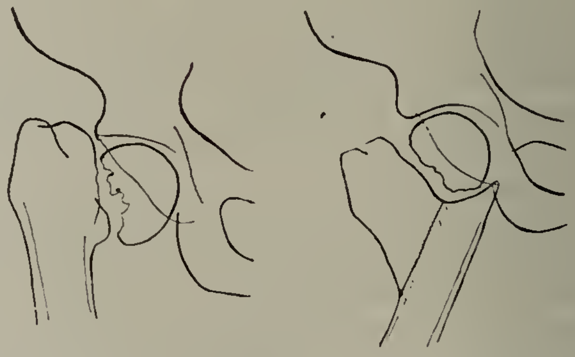

FIG. 6.—Shows, on the left side, a loose pseudarthrosis with marked dislocation upward of the great trochanter. The sketch on the right side shows the anatomical result of the bifurcation. In such cases the upper end of the lower fragment cannot be called a newly created head, because the normal head lies undisturbed in the socket; but it functions as a bony pillar propped against the lower rim of the socket, or, as it were, against the chin of the head. The pseudarthrosis is put out of commission. The head rests in the angle of the bifurcated femur.

It is an obvious fact that just in flexion adduction the hip joint is the least able to carry the weight of the body, because in this position of the thigh the iliac bone has to assume a more or less vertical direction, allowing the loosened upper end of the femur to slide up as soon as the weight of the trunk presses down the respective side of the pelvis, and to slide down when the diseased leg is in its swinging phase. Furthermore, the weakest posterior part of the capsule is put to strain with the thigh in this typical contraction.

By preliminary stretching and eventual severing of the adductor muscles, the adducted direction of the femur can be inverted in an extremely abducted (outward stretched) direction. By this forced abduction the iliac bone of the diseased side is lowered to a more horizontal direction, giving a kind of bony support to the top of the trochanter major. By inverting the typical flexion of the hip joint in hyperextension, the anterior ligaments of the capsule (Bertini ligament)—the strongest in the human body, equally are put to the commission of weight bearing. In this way the stretched soft parts at the posterior surface of the joint are relieved, and the source of pain is stopped.

I called this treatment of irreducible hip luxations and of old ununited fractures of the neck of the femur the method of inversion because the typical contraction, unfit for weight bearing, is inverted in the opposite contraction, in which the weight bearing, at least in part, is done by bony support and by the strong anterior ligaments of the hip joint. This treatment not only is without any danger and very simple, but it implies bed confinement of no more than a day or two. By adequate aftertreatment (plaster spica for some weeks followed by massage of the pelvitrochanteric muscles and active abduction exercises) the inverted position must be made habitual to the patient.

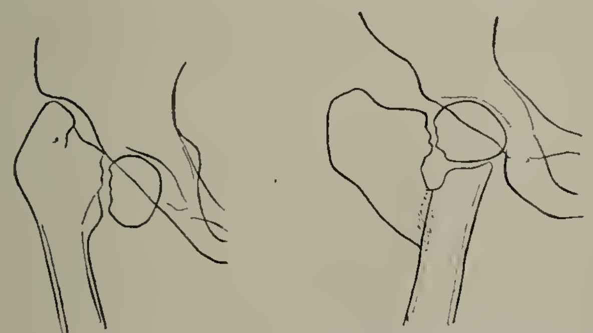

Fig. 7.—Seems to represent an analogous condition, but the left sketch belongs to what is called coxa vara luxans. After bifurcation the head is propped by the pillar of the shaft of the femur, as shown in the right side sketch.

Though the functional results of this bloodless treatment sometimes are surprising, it must be conceded that without proper aftertreatment inversion is likely to relapse. At any rate, inversion is the blandest means to improve, at least, the condition of aged patients suffering from pseudarthrosis colli femoris, and of adult patients with bilateral inveterate and irreducible luxations of the hip joints complicated by severe contractions. In the latter case it means not only correction or overcorrection of the contraction, but also may be considered as a pseudo reposition in so far as the posterior position of the head of the femur is changed into an anterior position, the posterior luxation being converted into an anterior one. Lordosis is corrected and the function of the hip joint is more or less improved. Should the result in the course of time become less satisfactory, bifurcation eventually may be added, because inversion does not prejudice bifurcation, but on the contrary might be considered as a preparatory or preliminary measure to the latter.

After the explanation of the idea and applicability of bifurcation in general, I have to describe the operation and its modifications in the special indications.

I begin with the cases which are characterized by an empty acetabulum (irreducible luxations of whatever origin—congenital, traumatic, tuberculous, osteomyelitic).

To create a large, wounded surface at the end of the fragments, the preliminary osteotomy has to be an oblique one. This oblique cut may be performed in a frontal or in a sagittal plane. In cases with an empty socket I have more recently followed a suggestion of my first assistant, Dr. Hass, to prefer the frontal plane. The plane of an oblique frontal osteotomy may be inclined forward or backward. The inclination forward recommended itself on account of the fact that this way the short superior fragment lies behind the lower fragment and is fixed by the latter: or we might say, the long lower fragment is at the same time an anterior fragment and is backed by the short superior and posterior fragment. Under these conditions the superior fragment should be prevented from slipping into a flexed position.

After the severing of the bone in a frontal anteriorly inclined plane, the upper end of the lower fragment is intentionally dislocated inward and somewhat upward to meet the anterior capsular wall of the joint. The socket being empty, there is room enough for the rounded ridge of the upper end of the lower fragment—it is large enough so that this rounded ridge, directed inward by abduction of the femur, can slide forward and backward on the anterior capsular wall, when flexion or extension is required. The chief advantage of the frontal anteriorly inclined section seems to be that abduction of the thigh does not necessarily imply a separation of the wounded surfaces, as abduction is carried out in a frontal plane.

On the whole, the question seems to be of no essential importance, as in many cases a sagittal section has given equally good results. Certain it is, however, that in x ray pictures the frontal cut makes a better tableau because the new head shows its rounded ridge not *en profil* but *en face*. Its crest is concealed, but it is not less sharp than in the sagittal cut.

The operation itself is quickly described when I omit all the aseptic and antiseptic preparations as a matter of course.

The patient is placed upon his sound side, the diseased thigh being slightly flexed so as to cover the site of the acetabulum. A longitudinal incision of about ten cm. is made through the skin and the muscles until the outer surface of the femur is laid bare. A broad chisel is then applied to the bone in an oblique line extending from the anterior aspect posteriorly and distally. The upper extremity of this cut should correspond with the upper level of the acetabulum. It must be a thorough osteotomy, and by no means an osteotomoclasy. When the bone is thoroughly cut and both fragments are isolated, the operator handles the lower fragment just in the same way that he is used to in the bloodless reduction work. After thorough abduction of the fragment, he pushes it inward and upward until he is sure of its new resting place in the empty acetabulum, that is, on the anterior capsular wall; the lower end of the upper fragment is pushed inward so as to form a nice angle at its junction with the inward, upward displaced upper end of the lower fragment. Intentionally I have abstained from any suturing of the fragments, their position being sufficiently assured by the abduction of the lower fragment. Tenotomy of the abductors is usually superfluous. Sutures of the fascia lata and the skin finish the operation.

While the plaster bandage from waist to toes is applied, the limb is held in abduction of about 35°, the assistant being advised to maintain the bony contact between the new head and the acetabulum by leaning against the limb. While applying the bandage, the operator takes care to tighten the rollers over the operative field, to maintain adduction of the upper fragment.

About a fortnight after the operation the patient is allowed out of bed and may begin standing and walking with crutches. After six weeks the bandage is cut and articulated at the knee joint to prevent rigidity. Serving the same purpose, the posterior part of the bandage over the calf of the leg may be removed to allow flexion exercises of the knee joint several times during the day. After two months the bandage is shortened to the size of a hip spica, leaving the knee free. Not before at least three months have elapsed may the spica be taken off definitely.

Aftertreatment consists of massage and gymnastics of the pelvitrochanteric muscles.

In cases in which the socket contains the head of the femur (pseudarthrosis colli femoris, coxa vara luxans) the preliminary subtrochanteric osteotomy is performed in a sagittal plane which is inclined toward the median line. At the operation the patient lies on his back. The skin incision is made at the anterior exterior aspect of the thigh, below the great trochanter. The bone cut is made in a sagittal inwardly inclined plane, beginning at the internal aspect of the femur at a level with the centre of the socket, and extending laterally and distally.

In dislocating inward the upper end of the lower fragment, it must be borne in mind that the socket is filled by the head, and that the crest of the lower fragment must find its mooring place somewhere at the lower or lower inner border of the acetabulum, eventually at the lower part of the head—as it were, at the chin of the head. A frontal cut would not do in these cases, as there is not enough room for the crest of the lower fragment, extending in a frontal direction.

The x ray pictures in these cases show the crest of the lower fragment in profile as the pointed end of the short prong of the fork. In this sort of case the cutting of the bone is done at a higher level than in the cases of irreducible luxation with the head standing high up. The upper, inner end of the cut should begin just below the trochanter minor, so that the osteotomy should still be of the subtrochanteric type.

This is, by the way, a question that often has been discussed at the operating table. In a subtrochanteric osteotomy, the upper fragment is under command of the ileopsoas muscle, and flexion might be the result; so much the more if the plane of the bone cut is a sagittal one. But so far we have not seen such an incident, or rather, an accident, which might endanger the bony union of the fragments.

Oblique intertrochanteric osteotomy just above the trochanter minor is scarcely advisable in cases of loose pseudarthrosis, which allows dislocation upward of the stump of the neck to a higher degree. Beside, there is always the danger of opening the joint with the chisel, which should be avoided at any rate. There is a possibility that the chisel might divide the trochanter minor into two halves, and that the handling of the lower fragment would become difficult on account of the insertion of the ileopsoas muscle. We have not met with this incident, which can be avoided by a high subtrochanteric osteotomy just below the trochanter minor.

In cases with filled, as well as with empty sockets, I have often made the mistake of gauging the upper end of the cut too low, but so far have not seen any bad consequences.

The cardinal question in my therapeutic endeavors was whether or not the intentionally dislocated fragments would undergo a firm bony union. The fact must be considered that usually the contact between the wounded surfaces is very small, and that in many instances the wounded surface of the upper fragment does not at all come in contact with the wounded surface of the lower fragment, but just touches the intact periosteal surface of the latter. The whole value of the operation is entirely dependent upon this question.

I dare say it cost me many a sleepless night, when I found out, in a certain case, that six weeks after the operation the union seemed to be quite questionable. There were moments when I had made up my mind to give up my endeavors as a failure. At this stage of my studies a special case in a quarrelsome, discontented woman of about fifty years, who complained all the time of her pains and her weakness (she had had pneumonia some weeks after the operation) threatened to drive me mad. As she insistently declared that she could not put her foot on the floor to make one step, I ordered a very expensive walking machine to get the woman out of sight at last. By the by, I did not like to see this woman, who seemed the embodiment of my troubled conscience. I stopped all operations, and suffered severely from my disappointment. About four months later the woman in question made her reappearance. She had discarded her machine and walked like a marvel. In order to have a souvenir of her which should teach me never to despair too soon, I brought that "hated" woman with me to America—in the shape of her moving picture.*

In the bifurcation operation, we can rely on the fact that subtrochanteric fractures, even if dislocated, have a great tendency to heal by firm bony union. Just as the fracture of the neck of the femur, by its incapacity to produce a bony callus, gives source to the trouble, so the subtrochanteric fracture lends itself to the relief of the same.

---

*While the material of this article has never before been published in America, the moving pictures referred to herein were shown, with comments, before the Society of Medical Jurisprudence of New York City on December 12, 1921, and more recently before the Eastern Homeopathic Medical Association at Trenton, New Jersey, on October 27, 1922.

In closing I have to repeat that bifurcation is not a radical but a palliative method. The luxation, the pseudarthrosis, remains as it was, but it has become excluded from its function of weight bearing and deprived of its bad sequelæ. One might say, it has been cheated out of being a source of suffering to the patient. Practically speaking, it means a cure, because the symptoms of the real as well as of the pseudoluxation are done away with. The characteristic limp disappears because there is no more sliding of the upper end of the femur on the outer surface of the iliac bone. Endurance in walking is very much improved, sometimes even reestablished, because the pelvis has direct bony support. The Trendelenburg-Lorenz symptom disappears. Some patients have become able to jump on their diseased limbs. Some of them walk with a scarcely perceptible limp, can jump, run and climb mountains. On different occasions I have demonstrated such patients at meetings of the surgeons in Vienna. The extent of the restoration of function and the cosmetic results exhibited elicited much general surprise and favorable comment, as they did when I exhibited their moving pictures over here in America.

We operated upon about sixty patients, a minute analysis of which will be given by one of my pupils at a later time. There still are some questions to be solved.

My bifurcation method cannot and will not compete with other reconstruction measures as far as the anatomical reconstruction of the hip joint is concerned. It will compete with them only in two respects: first, in the functional results—as far as these are concerned everyone may judge from the moving pictures; second, in the degree of danger involved in the operation—as far as danger is concerned, I may say that it is equal to zero. To avoid any shade of danger I am accustomed to perform the operation subcutaneously with the same good results.

It is beyond my understanding how such extremely dangerous operations as resections of the joint, including reconstruction of same by extirpation of the head of the femur and the creation of a longer neck by way of resection and dislocation downward of the great trochanter, etc., could be conceived and proposed to elderly patients, who evidently risk their life by the operation without being in danger of life by their ailment. In my opinion such operations can be considered only as a sign of desperation on the part of the surgeon in his hopeless struggle against an insoluble problem. In bifurcation even a failure will do no harm to the patient, not to speak of endangering life.

I must add a word on the really radical operation of bone grafting by the insertion of a tibia nail into the neck of the femur. This operation is much less dangerous than the resection methods, provided that the pseudarthrotic tissue between the fragments of the neck of the femur is left alone and the joint be not opened. Although it takes a very long time—not less than at least one year—before the nailed fracture can be trusted to bear the weight of the body, the final results may be beautiful, as I have seen in some of my own cases. But the grafting method can be applied only in fresh cases in relatively young and strong patients. In old cases of loose pseudarthroses, the chances of the grafting operation are, so to say, zero. The bifurcation operation has to deal only and exclusively with these loose, old cases of pseudarthrosis which baffle all therapeutic measures; therefore bifurcation does not compete with the grafting operation in fresh cases, but surely is superior to the latter in the old pseudarthrotic cases.

CONCLUSIONS.

Though etiologically different, irreducible congenital or acquired hip luxations and similar conditions, as ununited fractures of the neck of the femur, coxa vara luxans, etc., anatomically have in common the loosened connection between the pelvis and the upper end of the femur. Pelvis and trunk no more are directly supported by the bony pillar of the femur, being suspended only by the soft parts (muscles and capsule) upon the upper end of the femur.

Similar anatomical conditions account for similar functional symptoms, as flexion adduction contraction, dropping of the pelvis toward the sound side, limping, lack of endurance or inability to walk because of more or less severe pains due to the stretching of the soft parts by the weight of the body.

It makes no difference that in pseudarthrosis colli femoris the head is left in the socket, because the pseudarthrotic tissue between the fragments is put to stretch by weight bearing in the same way as the rest of the soft parts.

The similarity of functional disturbance in cases of irreducible luxations and pseudarthrosis colli femoris, etc., suggests similar, or rather, identical therapeutic procedures.

The problem to be solved is to change the elastic suspension of the body on the upper end of the femur, to a direct bony support of the pelvis by the femur.

As it is impossible to use the irreducible or deficient head (as in cases of pathological luxations) as a means to directly support the pelvis at the socket, a new artificial substitute for the head must be created.

This is done by an oblique cut of the femur at the level of the socket. The upper end of the lower fragment (the substitute for the head) by adequate maneuvres is reduced into the capsule covered socket, while the lower end of the upper fragment is brought into contact with the lower fragment, with which it will be united by bony tissue. In this way the upper end of the femur has become transformed into a fork with two unequal teeth, or prongs: therefore the procedure is called bifurcation of the upper end of the femur.

The characteristic feature of this operation is reduction into the socket of a newly created substitute for the irreducible head. Subtrochanteric osteotomy, then, is only a preparatory step to bifurcation. As reduction into the socket of a substitute to the head, bifurcation is clearly differentiated from all other subtrochanteric osteotomies in which the correction of the contraction is the only aim.

Therefore, bifurcation is a completely new operation of quite a distinct character, and this character is reduction by way of forcing the femur to make a side way to reach the socket instead of passing by.

In cases of pseudarthrosis colli femoris, the upper end of the lower fragment is displaced and propped against the lower rim of the socket, or, as it were, against the chin of the head which is contained in the socket. In this way the pseudarthrosis is put out of commission, the pelvis being sustained directly by the bony pillar of the femur.

Drawbacks to the operation are: some shortening (equalized by tilting of the pelvis), and some restriction of motion. Advantages are: the lack of danger, the relatively short time of treatment, as common in fractures of the femur, and the good functional results, which have been demonstrated in Vienna and in the moving pictures which have been shown in America.

Nevertheless, I consider the operation as the last resource, especially in cases of pseudarthrosis of the neck of the femur, while in cases of pathological luxations bifurcation is the only therapeutic measure available and should be resorted to always.

Although in possession of bifurcation, I have not given up my bloodless method of treatment in cases of irreducible, especially bilateral, luxation and in cases of old ununited fractures of the neck of the femur, especially if complicated by severe contractions of the hip joint. I call this bloodless treatment inversion because it aims at inverting the concomitant contractions. By overcorrection of flexion, the strong anterior ligaments fit for weight bearing are put to strain, while by overcorrection of adduction the iliac bone is lowered so as to come in contact with the trochanter major offering it a kind of bony support.

Though the functional results of inversion sometimes are surprising, it has to be conceded that without proper aftertreatment relapses may occur. Inversion does not prejudice a later bifurcation.

Bifurcation is not a radical but a palliative treatment. It does not compete with radical methods (resections—reconstructions—grafting methods) as far as anatomical restitution of the hip joint is concerned, but it competes with them in two respects: first, in the functional results which have been demonstrated as excellent; second, in the lack of danger. While danger in bifurcation is, so to say, equal to zero, patients subject to resection methods risk their lives without being in danger of life from their ailment.

The applicability of the bifurcation operation is manifold:

1. In cases of irreducible congenital hip dislocation.
2. Eventually in cases of refractory congenital luxations.
3. In irreducible traumatic hip luxations.
4. In pathological dislocations due to osteomyelitis or tuberculosis.
5. In the severest cases of coxa vara (coxa vara luxans).
6. In cases of pseudarthrosis colli femoris.
7. In cured cases of tuberculous hip disease complicated with frequent attacks of severe pain.
8. Eventually in cases of severe arthritis deformans coxæ in older patients, to control pain by relieving pressure in the joint.

The Lorenz Bifurcation Operation

A Preliminary Report

By DEXTER D. ASHLEY, M.D.,

New York.

Time and again patients have come to me with long standing deformities of the ileofemoral articulation—unstable, painful—due to disease, fracture, or congenital malformation. For these patients, in the past, I have been unable to suggest any satisfactory method of surgical relief without endangering life.

For such conditions this simple operation, almost bloodless and devoid of shock, reduces the danger to the vanishing point. In this respect the operation is on a par with the subcutaneous osteotomy of Gant for the correction of the bony or fibrous ankylosis of the hip in deformity, and the stable hip in adduction deformity, with its consequent shortening.

Various operations have been devised by our best orthopedic and general surgeons to stabilize these painful hips, among which should be mentioned Whitman's reconstruction operation, drastic operations by the late J. B. Murphy, and the bone graft, or peg, of Albee; operations fraught with great danger, and requiring a very precise and careful technic, their application being limited to those patients whose constitutional resistance would make them fair subjects for a major operation. This would exclude from operation the majority of patients so afflicted. The bifurcation affords a procedure that is admirable in its wide adaptability, giving as a result a surprisingly stable, movable hip.

Let us take, for example, a case of broomstick deformity of the femur: that is, loss of the head and neck due to disease or old fracture, which has left the limb in marked adduction and flexion, the line of weight bearing in such a flexed and adducted femur being directed outside the pelvis, the diseased or broken remnant finding no stability in the soft tissues on the sloping side of the pelvis. Until a year ago I did not feel capable of giving any relief in such a deformity.

TECHNIC OF THE OPERATION.

The patient, having been anesthetized, reclines on his unaffected side, bolstered up with sand bags, the well limb being flexed at thigh and knee, the limb to be operated upon being held by an assistant resting on a sand bag. The assistant is directed to hold steady, rotate inward or outward, or maintain the limb in a position of adduction-flexion, thus laying the shaft of the femur across the site of the acetabulum.

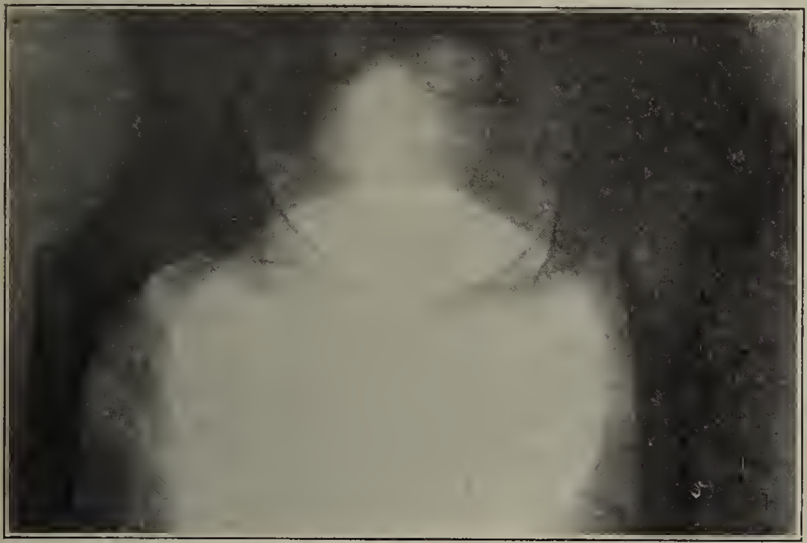

Fig. 1.—Case III.

The field having been prepared with the ordinary iodine application for surgical procedure, the surgeon measures from the top of the great trochanter to a point about opposite the centre of the acetabulum, this point having been plotted out on an x ray picture. Toward this point the chisel is to be directed.

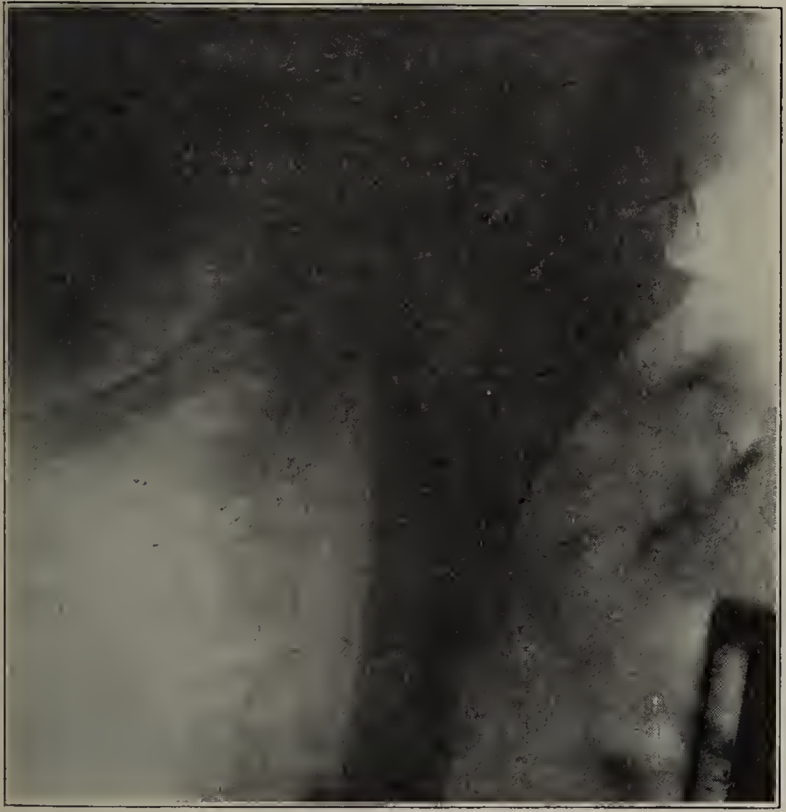

Fig. 2.—Case III.

A chisel of suitable width according to the size of the bone is inserted at a point below the acetabulum; a complete fracture of the bone is made, cutting obliquely inward and upward, or from behind upward and forward, executing an oblique osteotomy (Fig. 1). The distal fragment is thoroughly separated from the proximal fragment by the chisel, which is then withdrawn and the small opening sewed up with two or three stitches and covered with aseptic gauze retained by adhesive plaster. In subjects who are excessively fleshy a small incision is made down to the bone.

The bayonet end of the long bone is then dislocated or insinuated into the acetabulum (sometimes against its lower rim) finding a stable position. The limb is abducted until the line of weight bearing falls well within the pelvis. Any existing deformity is over corrected.

The assistant carefully maintains this position of the distal fragment by pushing gently upward, keeping it in touch with the pelvis and the knee straight. The proximal fragment is pushed inward and downward until its distal extremity comes in contact with the outer surface of the distal fragment. or the shaft of the femur. After union we have a forked shaped upper extremity of the bone, the outer arm of the fork formed by remains of the upper part of the femur, and the inner arm of the fork formed by the bayonet like point of the distal fragment, making thus the socalled "bifurcation."

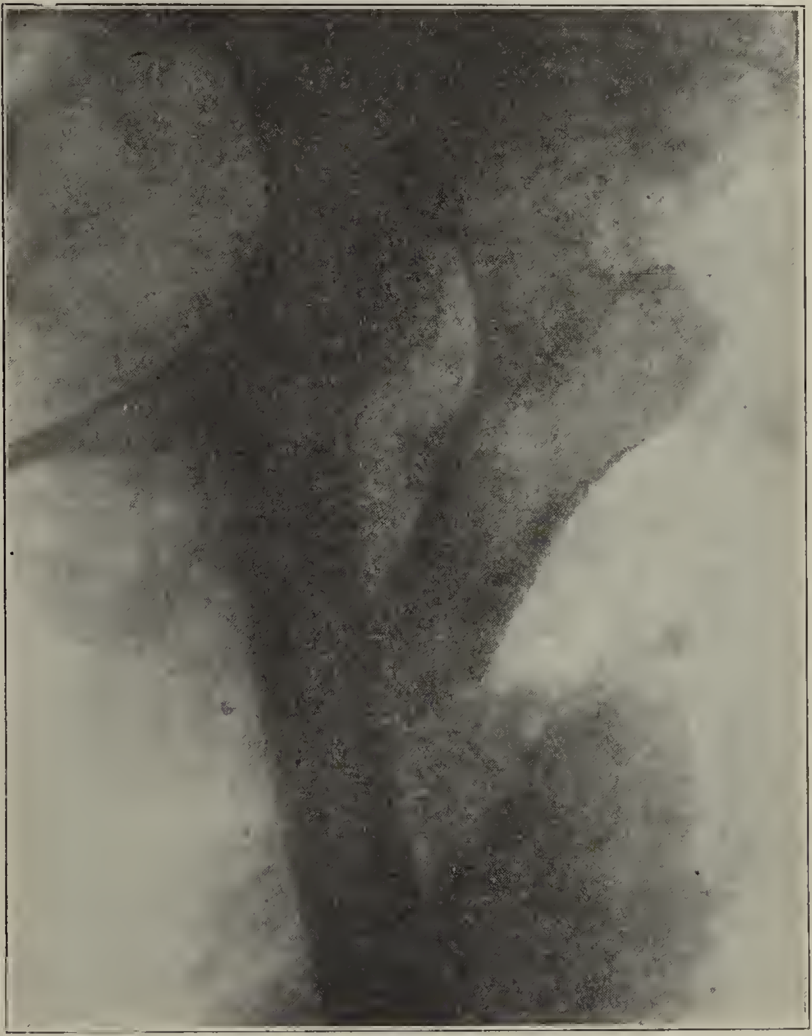

Fig. 3.—Case V.

A plaster of Paris spica is applied including the foot, care being taken to hold the proximal fragment in position by careful moulding of the plaster.

This oblique osteotomy is a matter of a very few moments; the dislocation and finding the stable position a matter of even less time; the whole operation, including the application of the spica, requiring only from twenty to forty minutes. The operation is almost bloodless with no perceptible shock to the patient.

The patient is usually sent home in plaster in from five to ten days. In two or three weeks he is directed to walk around on crutches. In from six to eight weeks the plaster is removed below the knee, permitting knee flexion and extension. In from twelve to fourteen weeks the plaster is all removed. It is desirable in all cases to follow progress by x ray.

When the plaster is removed the amount of movement of the hip may be small, but this movement will be found to increase gradually. After six months it is remarkable what feats of walking these patients will perform on a limb which was formerly comparatively useless, insecure, and painful.

The real distinction of this operation lies in the establishment of the upper extremity of the distal fragment of the shaft of the femur against the pelvis, near or within the acetabulum.

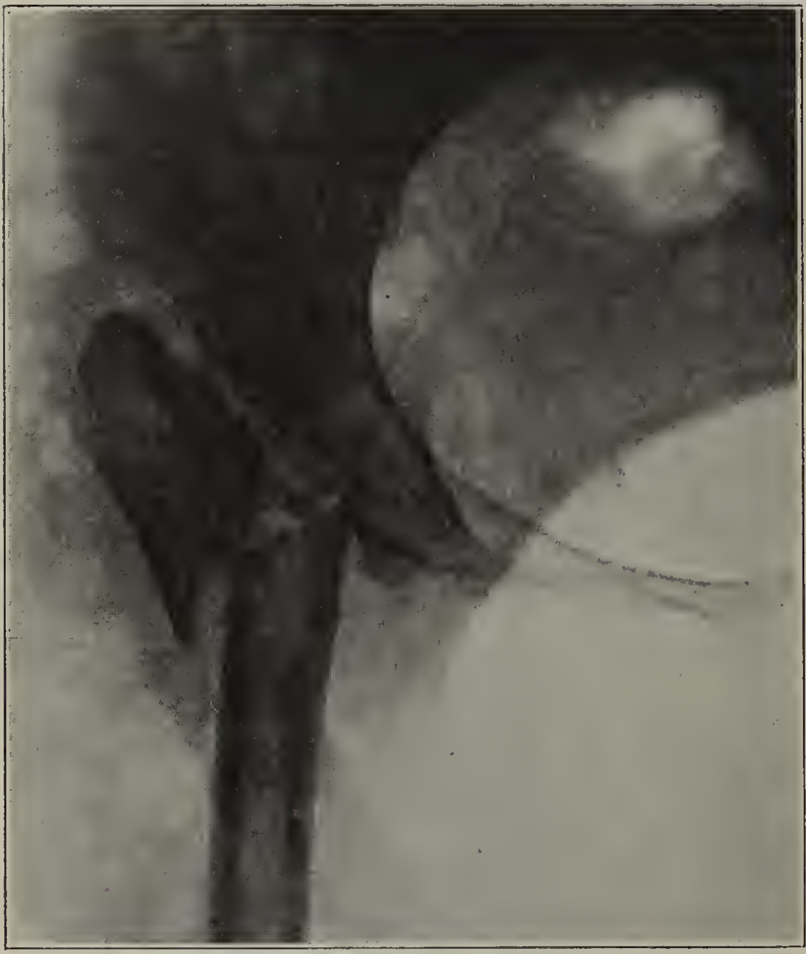

FIG. 4.—Case IX.

Upon first seeing an x ray of a bifurcation, one is astonished to note the bayonet point of the inner fork, and wonders why it is not a constant source of irritation. A fascia (or fat flap of Murphy) has been caught upon this inner prong of the fork, covering the end, which in healing becomes rounded, making a weight bearing point against the pelvis.

It is not asserted that the technic of this operation has been fully developed. Some operators may wish to do more open work, well exposing the bone in order to see the point of osteotomy to better advantage. A Gigley saw could then accomplish most accurate technic. As remarked before, this open work is desirable in fleshy subjects. There is a possibility that the bone may be cut higher or lower than is desired; if too low, or not sufficiently oblique, more shortening is produced; if too high, it is difficult to place the upper end of the distal fragment in or under the acetabulum, which is the real aim of the whole operation. In cases in which the acetabulum is partially filled by a diseased femoral head, or with the remains of the head after fracture, the proximal end of the distal fragment is placed just at the edge of the acetabulum, under the diseased or broken off head. So far in the history of the operation, the proximal fragment has always united firmly with the distal fragment, producing a true bifurcation.

The broad application of this operation can hardly be appreciated at first glance. Foremost of the conditions to be benefited is the old, ununited fracture of the neck of the femur. If this operation were applicable to this condition alone, it would be a remarkable addition to our surgical procedure. In the second place this operation is indicated in pathological, unstable conditions due to tuberculosis, acute infections, acute arthritis neonatorum. Third, it is available also in cases of old, painful congenital dislocations, or pathological dislocations after typhoid fever, osteomyelitis, and other similar conditions.

None of the conditions above summarized can be relieved by a Gant's osteotomy. The bifurcation operation gives a stable, movable hip. The amount of flexion permitted will largely depend upon the mobility of the proximal fragment upon the pelvis. It does not always overcome the entire shortening of the limb; in fact, it may be seen that it would make the limb actually shorter, but this partially, if not quite, compensated by the abducted position of the limb. The line of weight bearing is changed to direct support under the pelvic basin. The importance of this must be conceded. The stable, shortened limb can be compensated by an elevation in the shoe.

The history of these old, tuberculous hips is the record of many stretchings, forcible corrections of adduction and flexion deformities, with as many relapses into deformity. Many give a history of a Gant osteotomy, with relapse, especially in young and adolescent sufferers. This operation removes the weight bearing to a nondiseased area, providing a double weightbearing surface. We might say that the inner prong of the bifurcation is a peroneal crutch, relieving the weight bearing from the outer prong.

After this operation the limb is prevented from going into adduction deformity by its brace of the outer prong of the fork, or the position of the proximal fragment.

This operation is not recommended when the lowering of the pelvis to one side, which occurs after operation, would tend to make unstable the articulation on the other side, as would happen in double hip disease; or in the case where one hip is dislocated and the other partially luxated.

Dr. Lorenz has had films taken in Austria showing many of these cases walking, climbing mountains, and bearing burdens with great freedom and ease within six months after the operation. These films were shown recently at Trenton, N. J., by invitation, and some of the early films were shown at the Academy of Medicine, by invitation of the Society of Medical Jurisprudence, in December, 1921.

346 LEXINGTON AVENUE.

The Correction of Congenital Club Foot

By E. H. BRADFORD, M.D.,
Boston, Mass.

After correction of the club foot deformity it is important that in walking the sole of the foot should be placed normally on the floor at every step and not strike so that the chief weight bearing comes upon the fifth metatarsal. This may occur in small feet even though the displaced bones may have been placed in their normal relations. This will occur even in larger feet if complete correction has not been made of the misplaced bones especially in placing the cuboid in its normal relation to the os calcis. Where this is observed in a corrected foot it is due to the fact that the peronei have not gained the normal strength in balancing the opposing tibial muscles or that the ligaments are not normal in their tension or elasticity. A continuation of a confining bandage is manifestly contraindicated under these conditions. A shoe with a thick wedge on the sole under the cuboid and in some instances a light efficient ankle brace worn for a few months will enable the patient to gain through the normal exercise of the foot and ankle muscles a normal condition.

I am able to present testimony as to the permanency of the cure of talipes equinovarus. Several congenital cases of double equinovarus operated upon by me and one case treated in infancy by corrective bandaging without tenotomy were examined by me several years after treatment, in two instances twenty and thirty years after the cure. The condition showed an absolutely normal condition of the feet except that in some of the single cases the foot was slightly smaller than the other foot.

Before the anatomy of congenital club foot was accurately known cruder methods of treatment were often tried and advocated. It is evident, however, that the less the mutilation following the corrective methods used the better is the method, provided it is equally corrective. Furthermore, the more accurately the method employed fits the pathological anatomical condition the less mutilating will be the result.

When it was thought that the deformity resulted from a shortened condition of certain muscles cure was expected to follow tenotomy with a slight amount of correcting pressure. When poor results followed it was inferred that a deformity in the bones existed which necessitated excision of certain bones or tarsectomy to overcome misshapened individual bones not corrigible by pressure and tenotomy. After it was learned that the defect was due to a prenatal arrest not in the shape of the tarsal bones, but a congenital malposition of the midtarsal bones with resulting adaptive changes of the soft tissues connecting the tarsal bones it became evident that the bones could be saved from resection provided that they could be placed in their normal anatomical relations to the other tissues. To effect this it is only necessary to stretch or lengthen the abnormally shortened tissues which hold the distortion. It is also evident that if these resistant tissues are not all overcome relapses or imperfect results are to be expected. As the strength of the resisting tissues varies the suitable correcting measures vary in different cases. It is true that in many severe cases alterations in the bones have taken place but these are much less extensive than was at one time supposed and involving few of the tarsal bones do not prevent satisfactory correction and in young patients need not be considered as of prime importance as they are corrected in the later growth of the corrected foot.

Where but little change in the shape of the bones of the tarsus is present the correction of club foot may be regarded as the reduction of a congenital dislocation at the midtarsal joints, i. e., the astragaloscaphoid and the calcaneocuboid articulations. To prevent a relapse it is necessary that correction should be complete at both of these articulations. It is not sufficient to bring the foot to an apparently normal position simply placing the scaphoid in front instead of to the inside of the front end of the astragalus; it is also essential that the cuboid be placed in the normal relation to the front of the os calcis and in relatively the same plane and not on a lower level and to the inner side of the anteroposterior axis of the former bone. The obstacles to this reduction of the malposition in the tarsus is chiefly in the strong ligamentous tissues which hold the misplaced bones in their faulty position. If these are divided or torn and the shortened Achilles tendon lengthened by stretching or better in most cases by subcutaneous tenotomy the slight misplacements of the other bones of the foot can be easily overcome. The inward pointing of the end or the heel, the faulty inclination or the line of the metatarsal heads, which instead of being flat on the plane of the standing base is inclined upwards on the inner side, are all readily corrected after the chief characteristic of the club foot deformity, viz., the midankle dislocation has been removed.

In the exceptional cases where some distortion in the shape of the astragalus and cuboid exist experience has shown that very mutilating operative procedures are not needed even in adult feet.

In many cases after the most resistant ligaments have been divided and the Achilles tendon has been tenotomized the rest of the correction can be completed by manual force. This is almost always true in young children especially those who have not been operated on before and have relapsed. In the simpler cases and in younger patients complete correction can be effected by stretching with repeated plaster bandages usually with, but sometimes without, tenotomy of the Achilles tendon. In some relapsed and more resistant cases, however, more than manual correction is needed even after thorough division of resistant tissues.

It is unnecessary in this paper to refer to the various operative procedures in which sections of bone are removed. These have been employed by me in many instances in my earlier experience and have proved serviceable in giving good functional results. But they are all to a greater or less degree mutilating. Of these the least objectionable on this ground is ostectomy at the anterior end of the os calcis. Later experience has proved that even this minimum of bone removal is unnecessary if adequate correction by properly applied force is accomplished.

An admirable force applying implement in the correction of club foot is the well known Thomas wrench. This instrument, which consisted originally of an adapted monkey wrench, though efficient in skillful hands in twisting the front of the foot, is not mechanically a well adapted tool to force the anterior end of the os calcis to the inner side while the front of the foot is twisted out. A better implement is also needed to press the cuboid up while the astragalus and os calcis are held down.

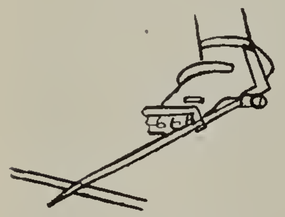

Fig. 1.—Club foot twister applied.

An implement of unlimited force as a club foot twister was devised some forty years ago to meet the surgical indications in the case of a woman thirty years of age with a severe congenital club foot. No attempts had ever been made to correct the deformity but as the woman had grown heavier she asked to have the foot amputated. The deformity was of the extreme resistant type, the patient walking on the side of the top of the dorsum of the foot. It was thought that if the desired amount of force was accurately applied sufficient to tear all obstructing ligaments and correct the deformity by placing the front part of the foot in front and not to the inner side of the midtarsal articulation at the same time twisting the front of the foot so that the cuboid and head of the first metatarsal should be placed on the normal weight bearing plane a cure could be accomplished. The risk encountered was that the foot would be so torn as to require subsequent amputation. It was, however, thought that there was enough elasticity in the main artery on the concavity of the distorted foot to stand the needed stretching and that the skin as is shown in osteoclasis could endure any amount of temporary pressure without sloughing. A long steel bar was placed at the inner side of the foot with a steel attachment so arranged as to hold the front of the foot in a firm clamp while the outer side of the astragalus and the outer and anterior part of the os calcis was held in a steel hook (worked on the long bar by means of a screw nut) pressing the midtarsus inward and downward while the requisite force pressed the front of the foot outward and upward. The handle end of the lever bar was furnished with a crosspiece so that the needed amount or twist could be given the front of the foot. The expected happened, a great amount of force was under the surgeon's hand and the deformed foot was warped into a normal shape. A tenotomy of the Achilles tendon was the only incision needed and that was done subcutaneously. A large tear of the skin and deeper soft tissues followed the correction but the tibial arteries were not injured nor were the nerves injured.

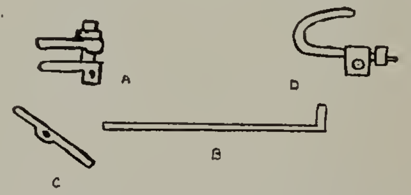

Fig. 2.—Club foot twister parts: a, toe clip; b, rod; c, handle; d, hook.

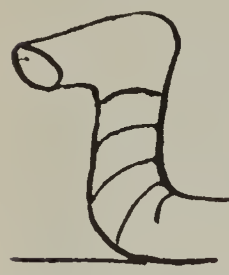

Fig. 3.—Position of limb while plaster of Paris bandage is hardening after correcting operation for club foot.

As the torn tissue could be thoroughly cleansed and afforded perfect drainage healing took place under an aseptic dressing without suppuration, the inch wide gap filling in with new formed tissue under the blood clot. The foot was put up in an overcorrected position of slight valgus and held in a plaster bandage, the foot being well padded with sheet wadding. The plaster bandage was applied to the whole leg and above the knee to prevent inversion of the foot through any rotation of the leg inside of the plaster. The retention bandage was applied while the patient was under an anesthetic, a window being cut to allow a change of dressing at the place of torn tissue. But few dressings were needed and no change in the plaster bandage. Crutch locomotion was permitted early. All bandages were removed at the end of six weeks. Three months after the operation the patient reported that she went to a dance but did not herself dance. The cure was recorded by casts before and after the operation and are placed in the Warren Museum of the Harvard Medical School. The patient was heard from a year later as in a condition of normal locomotion with no tendency of a recurrent deformity.

There have been a number of excellent club foot wrenches in use but in my experience the one here mentioned is the most efficacious in the larger and most resistant cases of sufficient size as to be too large for manual force. Its superiority lies in its greater precision in the application of the needed force in definitely correcting the most important bone displacements.

The resistant character of the smaller of the ligaments holding the scaphoid and os calcis in distorted positions often makes complete correction difficult. The surgeon is sometimes led to believe that if the foot has been forced into a normal shape it will remain so, forgetting that the elasticity of the stretched tissues may enable the bones to spring back to the distorted alignment. The most resistant of the distorting ligamentous tissues are those connected to the internal malleolus above, are continued down into the hollow of the foot and hold the scaphoid and cuboid in their faulty alignment. In the ordinary cases these tissues can be sufficiently stretched or can be freely divided by proper skilled subcutaneous tenotomy, avoiding injury to the nerves or important bloodvessels by keeping close to the bones and cutting inwards. In the more resistant cases the surgeon desires to assure himself that complete division had been made without injury to the artery and prefers to make an open incision. There is a great disadvantage in this from the large skin gap which is left in the correction of the foot deformity and which is not covered by suturing the cut skin edges together as the gaping opening is too wide and the skin elasticity is not sufficiently great in the neighboring region for satisfactory flap covering.

This difficulty of a large gap of uncovered wound tissue healing slowly under a blood clot can be avoided by the following procedure, which is not necessary in such cases as can be corrected by the use of manual or instrumental force.

Any surgeon trained in the use of the osteotome is able to make it a safe and serviceable, subcutaneous, surgical, blunt, dissecting instrument. A thin and somewhat narrow instrument should be used and the corners rounded off. Such an osteotome can be driven through the skin safely (without the previous use of a skin incision) at the lowest part of the internal malleolus. No vessels can be encountered if the instrument is driven down to the bone at its middle and not at the edge. The osteotome, after it is through the skin, can be pressed down in the loose subcutaneous tissue and used as a blunt dissector to free the attachment of the internal lateral ligament at the end of the internal malleolus and also all the attachments at the inner and under side of the hollow of the foot. As all the vessels are free of the bone they are uninjured by the osteotome if it is kept close to the periosteum. It is advisable to insert the osteotome freely between the scaphoid and the astragalus all along the edge of its apposition. It may also be advisable to insert the osteotome on the outer side of the foot to free, subcutaneously, the cuboid from any faulty attachments at the anterior end of the os calcis.

After these shortened tissues have been freely loosened from their terminal attachments subsequent stretching should suffice to enable the surgeon to overcorrect the deformity and secure it in a stiff bandage with the use of but little correcting pressure. Tenotomy of the Achilles tendon should not be done until all varus correction has been accomplished.

If the surgeon has succeeded in thoroughly correcting the deformity, the foot well protected with thick sheets of wadding can be immediately placed in a plaster fixation bandage and the operation is completed. If the correction is only made with the employment of considerable force, and there is a great tendency to a recurrence to the position of deformity, it is safer to defer complete correction or overcorrection until a second correcting plaster bandage can be applied; but as this requires an additional anesthetization, correction should be done at one sitting if possible, and this is usually possible. Abrasions and tears of the skin, if they are covered with aseptic cotton and the skin cleansed, give no trouble. It is important to protect the head of the first metatarsals as well as the phalanges by thick layers of cotton wadding to prevent pressure sloughs. The danger of these can be avoided by inspection which can be made by removing the upper part of the plaster bandage which has been cut as a bivalve so that the foot can be seen without displacing the corrected foot. The presence of pain after the day following the operation should be regarded as indicative of a threat of pressure slough.

It is well to remember that the two most important corrections to prevent relapses in resistant club foot are pressing of the cuboid, the varus and equinus, not only well from its abnormal position in relation with the end of the os calcis and well up from the weight bearing plane of the sole of the foot but also it is essential that the equinus position should be satisfactorily overcome.

It is often difficult in operating upon resistant cases after satisfactory correction to fix the foot in an apposition, adequately correcting the equinus deformity. This results from the difficulty in holding the heel down while the front of the foot is pressed up as the plaster bandage is applied and hardening.

A simple maneuvre will be found to aid in this. After the plaster is applied to the well padded foot the patient should be placed on his face and the leg held with the knee flexed at a right angle and pressed down upon the operating table. By pressing upon the sole of the foot operated upon, adequate correction both of the varus and equinus position is easily possible while the rest of the plaster bandage is applied and hardening.

It may be said in conclusion in regard to the subject of club foot and its correction that the surgeon can not escape responsibility for the result of his method of treatment. The deformity is eminently curable and in case of failure the methods employed have either not been properly carried out by the patient's attendants, or were not perfected by the surgeon in charge. Club foot is always amenable to the surgeon's skill if he is given a full opportunity to employ it.

When it is realized what a distressing deformity club foot presents its surgical correction and definite cure constitute an important advance in surgery. Future Lord Byrons, Talleyrands (to say nothing of Tamerlanes) will be able to follow the careers of their choice and to live without the sense of a curse of Heaven. The achievement in surgery has not been easily accomplished. From Stromeyer, Delpech, and Little to modern methods many years of effort and study have been needed. Recent progress has been gratifyingly rapid and today the successful procedures are easily learned by trained and painstaking surgeons.

The writer wishes to take the opportunity to acknowledge valuable suggestions in an interesting paper (1) by Dr. F. R. Ober, of Boston.

Dislocation of Foot.—T. Turner Thomas (*Surgery, Gynecology, and Obstetrics,* July, 1922) says that posterior dislocation of the ankle with fracture of the posterior tibial margin and Pott's fracture has received little attention in this country. The dislocation has been generally attributed to relaxation of the ankle joint resulting from the Pott's fracture. The prognosis will depend largely upon the degree to which the reduction of the displacements has been accomplished and maintained during the development of bony union. Without reduction the impairment of function must be serious. With reduction, the function has been essentially normal in all of my reduced cases except in two recent ones which have not yet had sufficient time to recover normal function. The reduction should always be proved by the x ray, and it should be maintained by a plaster cast because no other method will maintain the reduction satisfactorily. Moreover, for the same reason, the cast should not be removed until bony union is assured.

Foot Strain in Golf

By NORMAN D. MATTISON, M.D.,
New York.

There is probably no counsel given by the physician to his patient in need of the out of doors, which is carried out with so many variations as is the advice to "take up golf." Nor does the playing of the game, theoretically perfect for aiding in restoring physical and nervous balance, always result in the most salutary benefit. It is of interest, therefore, to consider some of the reasons for the frequent mental anguish and nervous unrest during a round of the links, the completion of which should find the player refreshed and renewed, instead of physically and nervously tired, as is so often the case.

Many of the difficulties attending the playing of golf have to do with a lack of coordination on the part of the player. And in a game which requires such exact control and distribution of the body forces, it is important for the player to know the factors which make for this lack of coordination, or disturbance of body balance. Only by understanding the synergies and conflicting forces of our bodies can the desired symmetry of motion, expressed as rhythm, be attained. Arrhythm, then, as it relates to golf, is caused by a lack of control of these forces as they enter into the performance of the strokes.

Obviously, the mechanics of a golf stroke consists of what one does with his or her hands, the body, the feet, and a club. It is no part of the purpose of this article to add to the endless confusion of observations about what one should or should not do with his hands, other than to suggest that the action of the upper extremities, as well as the control of the torso, is largely dependent on the control and support given by the lower extremities, especially of their bases.

Rather is it intended to direct attention to the feet as a factor in the control and maintenance of body balance, or equilibrium; to observe the causes and results of foot strain due to habitually faulty use of the feet, and resultingly, of balance; to comment on the various degrees of foot strains and distortions, as these are affected by and affect the playing of the game; and, finally, to propose the remedy.

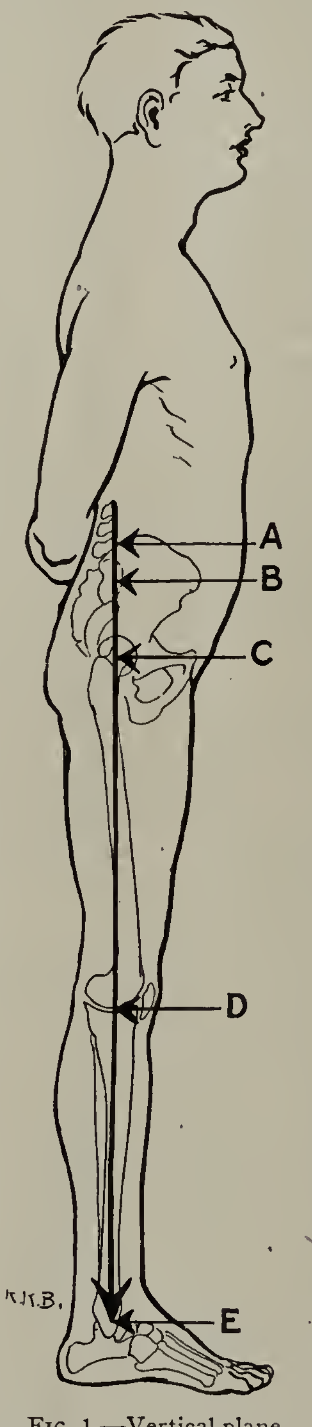

Fig. 1.—Vertical plane passing through the joints which transmit the body weight to the ground.

PEDAL EQUILIBRIUM.

In standing, in walking, or in carrying out any complicated manœuvre of the body, we are conscious of our relation to external objects. Conversely, equilibrium is the motor response to our concept of position. In the erect posture, equilibrium is maintained by our kinesthetic (muscle joint) sense, and any manœuvre of skill is dependent not only on muscles of sufficient strength and tone, but as well on the strength of the tissues composing the joints.

Consider, then, the feet as having to do with the maintenance of body balance. In the normal orthograde posture, the weight of the torso is conveyed along an imaginary plane passing through the lumbosacral, sacroiliac, hip, and knee joints, and finally to the base, the ankle joints and the feet (Fig. 1). For the body to be in its most stable equilibrium, this vertical plane must pass through the centre of gravity of the body (at a point opposite the lower lumbar spine), and fall within the base. The right control and distribution of the resultant forces and of the body weight operating to and through the ankle and foot is dependent, therefore, on pedal equilibrium.

On what arrangement of joint tissues, and forces operating on and to the joints of the feet, does this basic balance depend? The weight of the body is transmitted to the astragalus, retained in its tibiofibular mortise, and the os calcis, with which the astragalus forms the last and only ginglymus, or hinge, joint below the knee. The astragalus, composed as it is almost entirely of articular surfaces, and having no muscles inserted into it, is essentially a weight distributing centre. From the astragalus and os calcis the weight of the body is transmitted along two parallel lines of force, acting as a muscle joint couple through the mediotarsal joint (more properly, joints)—the outer series having the cuboid, the metatarsals and phalanges of the two outer toes, the inner series, the scaphoid, the three cuneiforms, and the metatarsals and phalanges of the three inner toes (Fig. 2).

Purposely, no mention has been made of the four usual designations of the arches of the foot. As they are described in texts on anatomy they are potential, rather than dynamic. The true dynamic arch of the foot is the transverse plane through the four segments composing the anterior tarsus (the three cuneiforms and the cuboid) (Fig. 3), and the articulations of these bones with the bases of the five metatarsals—the anterior tarsal, or transverse, arch. This arch acts as a tie, receiving the tensile stress of the usually described von Weber triangle—the inner and outer ball (the heads of the first and fifth metatarsals, respectively) and the centre of the under surface of the heel (Fig. 4). Here converge and are operative the tractive forces of three principal muscles on which the stability and action of the foot depends—the tibiales, anticus and posticus, and the peroneus longus muscles (Fig. 5). Here centre and are directed the antagonistic actions of the flexors and extensors, the inverters and everters, of the foot. The anterior tarsal arch, therefore, acts as a weight-controlling mechanism of the foot in action.

Two principal extrinsic foot muscles, the long flexors of the great toe and of the four outer digits, together with their reinforcing intrinsic foot muscles, are in control of forefoot propulsion, and resultingly, of balance (Fig. 5). The flexion efficiency of the great toe gives the same relative value to the management of this propulsion, as is the approximating of the thumb to the fingers of the hand.

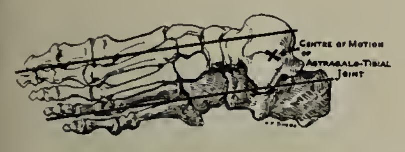

Fig. 2.—The outer (shaded) segments receive the weight of the body in walking. The inner (unshaded) segments distribute the weight, and deliver it forward for the succeeding step.

HABITUAL FOOT STRAIN.

Each of the segments of the foot has a normal, though limited, range of movement, without disturbing its centre of motion in relation to adjacent segments. And when the centre of motion (the convergence of its axes of motion) of any segment or segments is habitually changed, then there is some degree of beginning foot dysfunction. This applies particularly to the articulations of the anterior tarsal arch, which, like those of the mediotarsus, are all arthrodial, or gliding, joints.

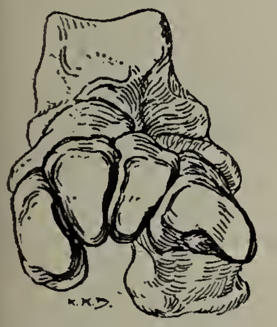

Fig. 3.—The anterior tarsal, or transverse, arch — the three cuneiforms and the cuboid. The minor degrees of shocks to which the foot in walking is constantly subjected is transmitted, like all other arches, toward its buttresses. Alterations of the bony relations of these segments, as a consequent on the loss of prehensile control, marks a developed stage of chronic weakened foot.

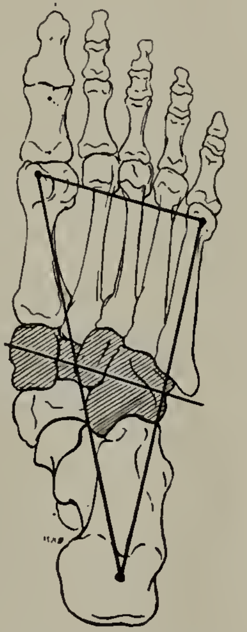

Fig. 4.—The anterior tarsal arch (shaded) acting as the tie of the weight bearing triangle of the foot. It is the transmission and control of the weight through this arch which determines the strength, or lack of strength, of the foot in action.

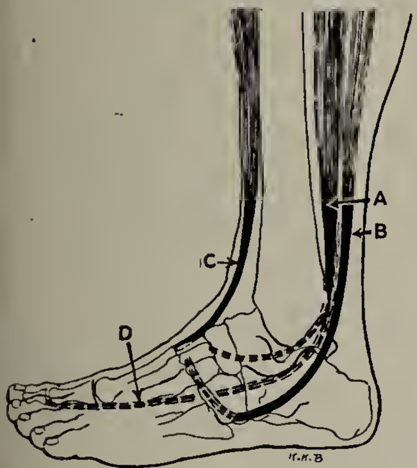

Fig. 5.—Showing in diagram the action of opponent muscles directed to the transverse arch, and the action of the great toe flexor muscle.

When weight distribution is controlled by normal pedal equilibrium there is no resulting foot strain, provided the parts are not taxed beyond their capacity to withstand strain. Again, when all the segments of the foot glide or move within their normal range, and there is the requisite intermittent contraction and relaxation of the muscles, their tendons, and the ligaments of the joints, the foot has attained its greatest possible stability of equilibrium in use.

The prevalence of weakened foot, in its progressing degrees from chronic foot strain to pes planus, needs no comment here. Well enough to attribute modern foot ills to vicious shoes, the shape and fit of which are so often dictated either by prevailing fashion or the shoe salesman; to shoes which are too short, too narrow, or with too high heels; to too short socks or stockings; to constant pressures from walking on hard, unyielding surfaces; to occupations requiring standing—contributing factors, any or all, to foot dysfunction.

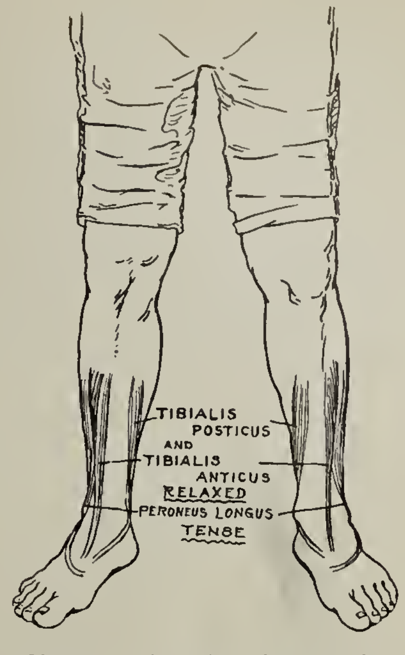

Fig. 6.—The feet in eversion, showing in diagram the lack of control of weight bearing, and of disturbance to normal muscular action. (Compare with Fig. 7.)

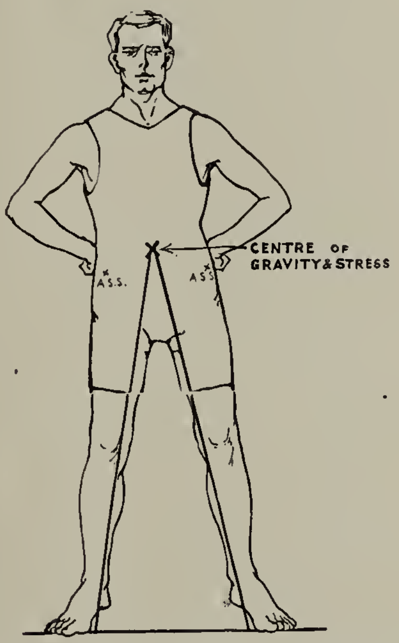

Fig. 7.—The body in balance, the feet positioned so that the weight transmitted through the lower extremity is received entirely within the foot.

On what habitual factor, then, does chronic foot strain, and its concomitant, weakened foot, depend? The degree of weakness of the foot is in direct ratio to the lessening or loss of the prehensile sense and control, which dominates the flexion or grasping action of the forefoot. The development of the all too common everted, or splay, foot is the direct consequence of this lessening or loss of prehensile action. Thus, when the feet are everted, or turned out, the inverter muscles of the foot (tibiales) are comparatively relaxed, and the everters (peroneii) placed unfavorably for normal contraction (Fig. 6). (Witness the frequency of peroneal spasm in advanced stages of weakened foot.)

In order to compensate for lack of muscular strength and of resilience of ligaments the feet assume the broadened base of relaxation,

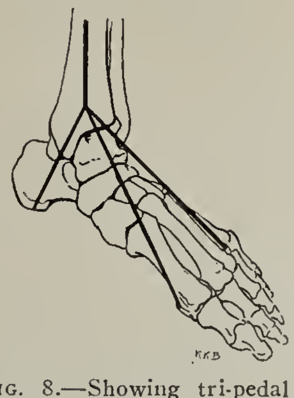

Fig. 8.—Showing tri-pedal base of support, and direction and distribution of the lines of force acting through the astragalo-tibial joint. When the weight in walking is transmitted properly to the heads of the metatarsal bones, these bones act as buffers, or "shock absorbers."

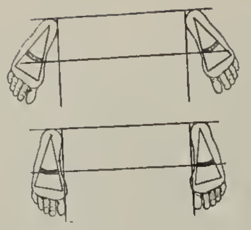

Fig. 9.—The "four square" base of support, giving the greatest stability within the smallest area. Contrasting, the comparative weakness of the base of support when the feet are everted.

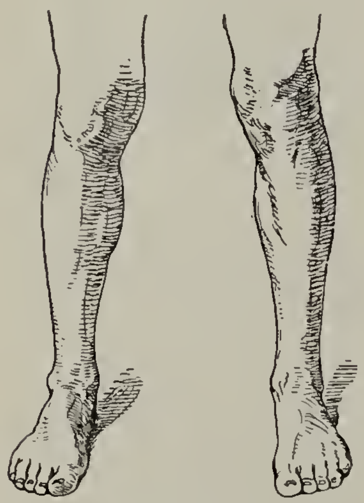

Fig. 10.—a.

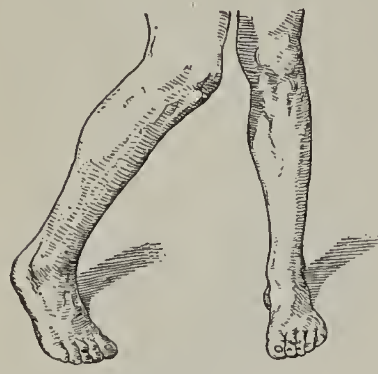

Fig. 10.—c.

Fig. 10.—(Line drawings from photographs.) a, The feet properly positioned; b, the feet as they are positioned when the body is in extreme right rotation, (the "top of the swing"), the entire left forefoot being in contact with the ground, and the left heel raised but slightly; c, the feet when the body is forcibly turned in rotation to the left, the finish of the full stroke, or "follow through."

weakness, inhibition, and the grasping action of the forefoot is thus interfered with. Weakened foot, therefore, has its inception in neglect, lack of control, and resulting inhibition of muscle balance.

WEAKENED FOOT AND GOLF.

The average person thinks little, and apparently cares less, about his feet, so long as they carry him reasonably well through the activities of the day and do not trouble him excessively. He may realize that he walks an average of about five miles a day, but he may not be conscious of the fact that in this distance he takes something over twelve thousand steps, these latter controlling an aggregate of over eight hundred tons.

If this average person happens to play at golf, he interrupts his habitual method (or lack of method) of walking on the hard pave, and changes his usual footwear for shoes which may or may not be best adapted to the purpose. He begins playing by assuming the splay foot position to which he is accustomed, his feet spread apart sufficiently to give him something a sense of balance. After surcharging the mind with the many things he is supposed to do or not to do, then follows the attempt to respond to a most exacting demand for coordination. With the feet everted, and when body rotation to the right has reached its maximum (in golfing parlance, the "top of the swing"), the left foot is bearing the weight imposed on it mainly on the great toe, the outer ball of the left foot not being in contact with the ground at all. Indeed, as will be pointed out later, the stroke is about to be played, as with all the ones to follow, with the feet positioned so as to give them, and resultingly the body, the least possible stability and the greatest stress.

After playing the stroke, walking is again resumed over a greater or less distance, usually less, under conditions of foot usage totally different from those to which he is accustomed. The feet have continually to adapt themselves to yielding and uneven surfaces, to changing planes of inclination. The usual methods of positioning the feet are followed, according to the required stroke, on to the end of the game. At no time have the feet been so placed that they are best adapted to the control of body weight, to the rotation of the torso, to counterbalancing the movement of the arms, and to the application of force. The reason for this will also be demonstrated later. Briefly, in order to attain the maximum of strength and stability each foot must be positioned and used so that the weight is controlled within the foot, along a plane projected forward from the centre of the heel and passing through the second metatarsal bone (Fig. 7). In the everted, splay foot, this plane passes to the inside of the great toe, with resulting stress imposed on the transverse arch of the foot, and inhibition of forefoot action.

Indeed, it is doubtful if the vast accumulation of inhibitory influence, as these affect pedal equilibrium, can at once be adjusted to adequate controls. Feet that are weakened from habitual misuse and neglect, feet that are chronically strained, are not readily adapted to the exacting demands of golf, the playing of which serves only to accentuate the degree of weakness and strain already existing. Is it small wonder, then, that a game so potent of good for the many thousands who play it, brings often only a

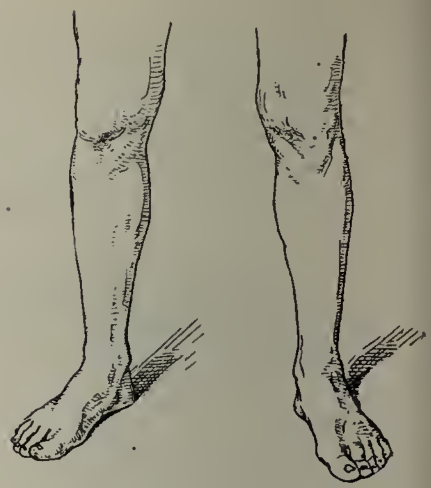

Fig. 11.—a.

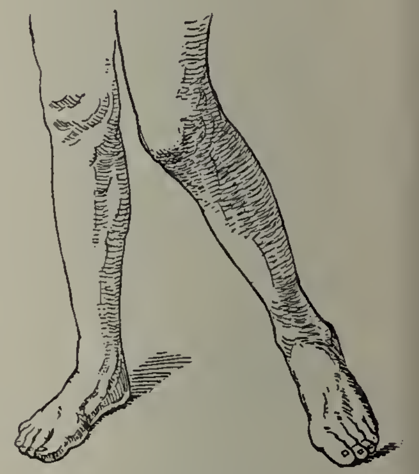

Fig. 11.—b.

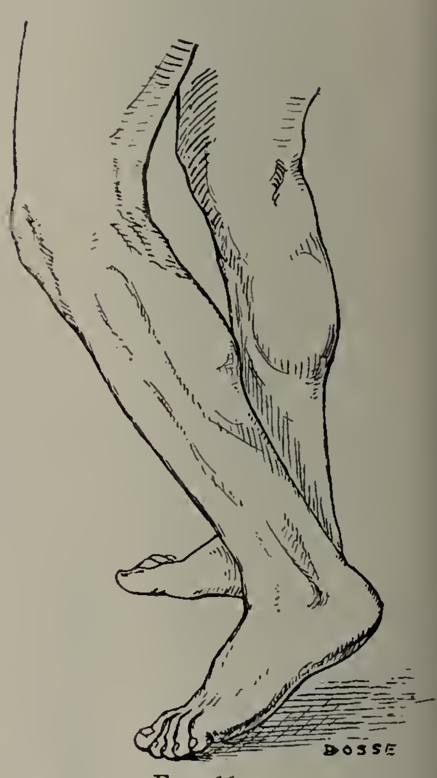

Fig. 11.—c.

Fig. 11.—(Line drawings from photographs.) a, The feet as they are usually, and wrongly, positioned at the beginning of the full stroke; b, at the top of the swing, showing the small, unstable base afforded by the first toe alone, the lack of contact of the outer ball of the left foot with the ground, and the extreme elevation of the heel—all of which creates the least possible stability where this is most needed; c, same as preceding, showing side, instead of front, projection.

modicum of health benefit and enjoyment? So far as concerns the lack of muscle balance and of pedal equilibrium, mute evidences of some degree of foot dysfunction which so many bring to the playing of the game, it would appear that there is something radically and persistently wrong which needs correction.

RESTORATION OF BALANCE IN GOLF.

The anterior portion of the foot operates in controlling the weight directed to it through the lower extremity (Fig. 8). Again, the lower lumbar region acts as the centre of motion of the entire body. Not only is this latter region also the centre of gravity, but as well the centre of stress of the body. In any body manœuvre requiring skill, the accuracy of the performance depends on the control of these conjoined centres. If there be an inadequate base, due to faulty position or lack of intrinsic strength of the feet, there must result a disturbance of the kinesthetic sense dominating the control of these centres—a too rapid or a too slow shifting of the centre of gravity, and with it the centre of stress—and the effort is lessened in its efficacy.

Obviously, therefore, stability of the base is a requisite in the playing of golf. In the back swing, the hands and the club operate together as a counterbalance, directing an arc of motion around the body, and the torso rotates up to a resistance point beyond which no further rotation is possible. At the "top of the swing," the counterbalance of the extended arms, together with the turning of the body, has created the maximum requirements of equilibrium. It is at this point at the end of the arc of motion, therefore, that the greatest stability is requisite. Here the comparative relaxation of the muscles acting in right rotation begins to give place to the contraction of the antagonistic groups, which act as left rotators of the torso. Indeed, it is the sense of disturbance of muscle balance engendered by this change which makes the player tighten up too soon in his efforts to maintain his equilibrium, the left rotators begin their work before the body has completed its pivoting around its centre of motion, and the stroke is thereby spoiled.

How, then, is correct control and coordination to be attained? By positioning the feet at the beginning of every stroke—long, intermediate, or short—so that the ties (anterior tarsal arch) of the weight-bearing triangle of each foot shall be in the same plane, and therefore in alignment, and with the feet separated only enough to maintain equilibrium during the stroke—in other words, the inner margins of the feet at all times form a parallel with each other, the feet being in alignment (Fig. 9).

Thus, under all conditions of play, inclusive of the walking between strokes, the maximum of stability is attained with the least possible joint and neuromuscular stress, whether this have to do with the body or with the feet. The entire left forefoot during right rotation of the body will therefore be constantly in contact with the ground, instead of only the limited base of the great toe alone when the feet are everted (Figs. 10 and 11). There is no hampering of the pivoting of the body, the lateral sway of the hips is practically eliminated, there is the least possible disturbance to the centre of gravity of the body, and there is provided a maximum of force with a minimum of stress and resistance. The power exerted is thereby concentrated and is not dispersed in the efforts to maintain equilibrium. And, finally, the degree of strain is lessened, not only as affecting the feet, but as well there is a lessening of the socalled rheumatic pains, the result of overstress, so often referred to the knee, hip, sacroiliac, and lumbosacral joints as the result of foot unbalance, or disturbance of pedal equilibrium.

CONCLUSION.

It is not within the scope of this article to elaborate the practical phases of the restoration of balance, as they enter into the playing of the game, except to observe that golf needs a new vision and a better understanding. Nor is it intended to suggest changing the methods of players who, due to long practice or a natural aptitude, have attained the desired skill and control, provided the feet withstand the degree of stress to which they are subjected. Rather, its purpose is to direct attention to the lack of physical equipment as this relates to its expression in body equilibrium, with especial reference to pedal equilibrium, which the large majority of golfers bring to this great health pastime.

Massage in Sprains, Dislocations and Fractures

By PIERRE KOUINDJY, M.D.,
Paris, France.

THE THERAPEUTIC APPLICATION OF METHODICAL MASSAGE.

Before we begin the massage of a member, we divide the member into three segments, according to the method of the Russian physician Goliakhowsky, the superior segment, the middle segment, and the inferior segment. For the lower extremity, the thigh is the superior segment, the leg the middle segment, and the foot the inferior segment. In case of the upper extremity, the superior segment is the arm, the middle segment is the forearm, and the inferior segment is the hand.

Massage is begun at the superior segment, followed by the middle and finally the inferior segment. This helps to reestablish the venous circulation and makes the mechanical action more effective. When the three segments are prepared in this manner one may proceed with the massage of the entire member.

In traumatic cases where there is a break in the continuity this method has been modified as follows, dividing the field into three parts:

1. The superior part, which is above the lesion.
2. The inferior part, which is below the lesion.
3. The middle part, which corresponds to the area

surrounding the lesion. The massage is begun with the superior part, then the inferior, and last the middle part.

MASSAGE OF SPRAINS AND DISLOCATIONS.

Tibiotarsal sprain.—The massage may be executed; (1) in the reclining posture or (2) in the sitting posture.

In massage of a sprain of the ankle in the reclining posture the leg of the patient should be placed upon a long cushion in such a way that the external anterior surface of the leg is turned upwards. The part to be massaged is divided into three parts; (1) above the articulation; (2) below the articulation; (3) the articulation. Complete massage for the superior part, superficial and profound rubbing, pressure, kneading, percussion, and if possible patting and vibrations (manual and mechanical). Partial massage for the inferior part, the foot, rubbing and pressure, mostly digital, along the tendon sheaths. The massage of the foot is terminated by bracelet rubbings.

After three or four days the third part of the massage is begun; superficial and light rubbing all about the articulation, light circular pressures, followed by profound pressure. Finally when the pain has abated we terminate each session by a general massage of the entire limb which consists of profound rubbing and pressure. Later we apply patting and kneading to the peroneal group of muscles and to the flexors of the foot. The posterior surface of the leg, the thigh, or the plantar surface of the foot should not be massaged.

At the termination of each session of massage, passive, active and resistance movements are applied for a very short time, and methodical movements are applied to the ankle. In order to keep the articulation in position a band of elastic tissue with lateral traction is applied in order to exaggerate the rotation of the foot outwards.

The application of this band requires a certain amount of dexterity, a special turn of the hand, placing the band about metatarsus so as to draw the foot outwards. The bandage is started at the base and carried upwards above the tibiotarsal articulation; while the heel of the foot is held with one hand, the band is brought up the inferior third of the leg. The bandage is then given another turn about the heads of the metatarsus and again around the leg. This forms a stirrup in which the foot is firmly held. Then we draw on the band while the foot is placed in forced outward rotation.

This position is fixed by extra turns of the bandage which is carried high up on the leg. In this way the foot is held in a position of rotation and outwards, where it is held for the required period. In any case, this position leaves the peroneal muscles free and prevents the foot from turning inwards.

In the sitting posture, the foot is placed on a stool. The field of operation is divided into three parts as in the preceding case.

I prefer the reclining posture, because in this posture the patient becomes less fatigued.

In case of large vascular exudations, padded compression should be applied after each massage. Preceding each session a hot bath should be given; this will hasten the recovery which varies from four days to two weeks. The foot should not be held immobile for a prolonged period, and no plaster appliance should be used.

Sprain of the knee.—In sprain of the knee three sections are massaged, the thigh, the leg, and the knee. Complete massage for the thigh includes rubbing, pressure, kneading with rolling and pressing, patting and percussion. Do not massage the posterior surface. Complete massage of the leg includes the anterior external surface only. Finally partial massage of the knee; begin with superficial rubbing, and light pressure; massage of the lateral ligaments of the knee and about the patella, where it is well to apply gentle pressure in order to hasten absorption of the exudate. Terminate the treatment by general massage of the entire leg.

It is important at the beginning of the treatment to establish compression by using a Velpeau bandage. Later after the reabsorption of the infiltration, and the pain has lessened, methodical movements alone are employed.

Sprain of the wrist.—In a complete massage of the superior portion of the forearm, avoid the flexors of the fingers if there is any contraction of these muscles. For partial massage, rubbing and pressure of the inferior portion of the hand. Finally slow and circular pressure on the ligaments of the carpal and the lateral ligaments; digital pressure upon the articular interspaces. From time to time palmar pressure is applied in order to stimulate the absorption of the infiltrations of the articular capsule. When the pain has perceptibly diminished, massage of the entire member may be started. This should always be in the direction of the venous circulation. The massage is terminated by passive movements, methodical movements, active and resistance movements.

In executing the massage for sprains of the wrist it is well to examine the carpal bones to determine whether there are any displaced. In this case it is well to employ stronger pressure upon the displacements in order to obtain a reduction. Often it is necessary to reduce the intraarticular exudates in order to facilitate the replacing of the bone to its normal position.

Sprain of elbow.—Complete massage of the superior portion, the arm and especially the triceps, as the biceps are often found contracted. Complete massage for the inferior portion, the forearm, the two antagonistic groups at the same time. Finally apply partial massage of the elbow. Here pressure and rubbing are of great assistance, rubbing for the entire region of the elbow. Digital pressure with the two thumbs below the olecranon process and simultaneously upwards, turning at the bone and ending at the two condyles of the humerus. At the olecranon cavity we should stop a bit and apply permanent digital pressure in order to relieve the congestion of the cellular tissue, which has filled the cavity. Complete the massage by passive movements. At the beginning of the treatment one should avoid active resistance movements. It is well to have the patient use his arm as soon as possible.

Dislocation of the shoulder.—As for the sprains, I select the most common types of dislocation in order to describe massotherapeutic intervention. The reader may establish his own method for the other dislocations from this one.

Massage for the dislocation of the shoulder should not be attempted until after the complete reduction of the articulation. Massage should begin immediately after reduction. The patient is seated in a chair. The operator assumes a position facing the shoulder of the patient. Begin with rubbings of the trapezius, the deltoid and the other periarticular muscles. This is followed shortly by light pressures. The trapezius is massaged from above downwards, the deltoid from below upwards; the middle portion vertically, the anterior and posterior portions of the humeral insertions towards the clavicle and towards the spine of the scapula. Massage the muscles above and below the spine from without inwards and in the form of a fan; massage the rhomboid muscles obliquely from the vertebral column towards the scapular insertions.

After several sessions of this massage, when we judge that the articulation is strong enough, we change from the rubbings and pressure to kneading, vibration and even patting, in the same way as for the methodical movements of the shoulder.

The active movements may begin when the movements have obtained a certain amplitude. Later the patient should attempt to take his arm out of the sling two or three times daily and attempt a few movements of abduction, flexion and extension. The arm should be carried in front, to one side and behind the body. Never neglect to put the arm in a sling after each session, especially at the beginning of the treatment.

It should be noted that often the articulation shows a certain amount of enlargement of the articular capsule, due to the congestion of the fibrous tissue of the articulation. In order to relieve this congestion it is necessary to employ digital or palmar pressure about the entire articulation, and a little more about the bicipital groove, where the tendons of the biceps are found.

The first sessions of the massage for the dislocation, as for all other dislocations, are destined to cause the absorption of the exudates. At the other end we utilize profound rubbings and pressure. If the infiltrations persist, we should resort to stronger measures, profound digital pressures, and at times grinding movements.

Dislocation of the elbow.—The same massage is applied for dislocation of the elbow as for sprain of the elbow, this being but an exaggerated form.

Dislocation of the wrist.—The same treatment is applied for dislocation of the wrist as for sprained wrist.

Dislocation of the fingers.—For dislocation of the fingers apply massage after reduction; rubbing, pressure, and methodical movements. It is useful to apply a bandage after each session of massage until the disappearance of the edema.

METHODICAL MASSAGE OF FRACTURES.

At the beginning of the world war I showed in an article published in the *Presse Médicale*, of August 26, 1914, my method for the treatment of fractures. I think that this method is the most rational one in use at present. I shall quote here that part of the article which deals with the treatment of fractures in general. "For us, we say, all fractures after their reduction should be placed in an immobile apparatus for a period varying from three days to three weeks, that is depending on their location; for example, fracture of the ulna or malleoli. After this we may begin the massage. The limb should be carefully taken from the plaster or apparatus and replaced with the same care. In order to massage the wounded member it is placed either upon a cushion of sand, or upon a blanket folded into eight thicknesses, and so far as possible in the same position as it was held in the plaster. The field of massage is divided into three parts; above the fracture; below the fracture; and the region of the fracture. The first portion is always massaged first. The only thing done during the first session is superficial and profound rubbing, executed gently and without effort. The same treatment is used for the second part. Do not touch, during the first session, the region where the callus fibres are located, in order not to cause hyperformation. The session of massage should terminate by rubbing the entire member, and avoiding touching the middle portion.

"The first sessions should not last longer than ten or fifteen minutes. The wounded member is replaced, with all the necessary precautions, into the plaster. On the first day of the massage the limb is taken out of the plaster cast and the cast is replaced by an ordinary bandage or a Velpeau bandage. In this way a gradual progressive compression is caused for the entire member.

"In the following sessions the preceding maneuvers are completed by pressure, percussion and the kneading of the muscle mass. All of these maneuvers are destined to combat the muscular atrophy occasioned by the immobility of the member. Finally we employ movements of the articulations, preceded by passive movements of the distal articulations.

"It is not until later, when the fracture is almost completely consolidated, that we begin the passive movements of the articulations adjacent to the fracture. Methodical massage notably shortens the duration of the treatment of fracture. It is important not to retard its application.

"As soon as we consider the fracture entirely consolidated, the cast may be abandoned and the movements of reeducation begun, for immobility, when more or less prolonged, causes a certain incapacity of movements in the wounded member. It is necessary to teach the patient simple movements, followed by more complicated movements. This way he will recover the functions of the muscles as rapidly as possible. Mechanotherapy, no matter how rudimentary, renders a great service.

"It is to be noted that the advice here given at the beginning of the war was not everywhere followed, for there are a great many cripples who, due to the rapid treatment of fractures among our wounded, present at times multiple ankylosis, vicious consolidations impossible to correct, and one is often disposed to inquire whether the wounded were looked after by a man who possessed the art of healing."

The preceding generalities are, it is understood, for application to the fractures of the larger bones, double fractures and complicated fractures. When the fractures are simple, as fracture of the tibia, metatarsal, etc., the plaster may be replaced by splints, or padded zinc gutters, or wire frames.

Fracture of the clavicle.—At the beginning of the treatment of fracture of the clavicle massage without moving the articulation of the shoulder is used. On the first day, if the general condition of the patient permits, I begin the movements of the articulations of the fingers, the wrist, and the elbow. At first the deltoid is massaged, rubbing with gentle pressure; massage of the trapezius, from above downwards, and the clavicular region with rubbing and digital pressure. At the end of from five to ten days of massage of all the periarticular muscles, profound rubbings, kneading and manual vibrations are begun. When the fracture is sufficiently consolidated, begin methodical movements of the shoulder.

Fracture of the scapula.—In this case partial massage of the periarticular muscles is applied. Avoid profound pressure and kneading of the infraspinous muscles, especially during the first four or six sessions. No movements of the shoulder should be made at the beginning of the treatment or before the wound is entirely healed. When the pain has ceased, profound pressure may be employed as well as kneading. The movements of the distal articulations may be started at the beginning of the treatment. Active and respiratory movements should terminate each session. A sling is applied at the beginning of the treatment, which may be taken off when the consolidation is complete.

Fracture of the humerus.—Massage of the deltoid: rubbing and pressure. Massage of the supraspinous and infraspinous groups of muscles: the pectoral and trapezius muscles. Massage of the triceps. Massage of the biceps is to be avoided in case there is a tendency to contracture. Massage the elbow and completely massage the forearm.

Treatment is begun by massaging the portion situated above the fracture; then the portion below, and the middle portion is not touched before the consolidation is complete. One must insist upon the movement of the wrist and fingers while the arm is held in the immobile position.

The methodical movements of the elbow and shoulder are begun as soon as the wound is practically cicatrized. The massage of this fracture is terminated by a general massage of the entire arm, superficial rubbing, and profound bracelet rubbing.

Fracture of the inferior extremity of the radius.—Place the forearm which has been taken out of the plaster or the splints upon a cushion which has been placed on a table or upon the knee of the operator. Institute partial massage, rubbing and pressure, of the two portions, superior and inferior. Never neglect to massage the hand. Use no movements during the first two or three sessions, except for the articulations of the shoulder and the fingers. Follow this by a moderate movement of the neighboring articulations—the shoulder and the wrist. At the moment it is possible to utilize the rubbing, pressure, kneading and vibrations, they are added. Later percussion of the fleshy part of the muscle mass is used. Insist upon digital pressure on the tendons, the ligaments, and the interossli muscles. Terminate each massage by a general massage of the hand and forearm, and if the immobilization has been somewhat prolonged, add massage of the arm.

Fracture of the bones of the hand.—Institute complete massage of the muscles of the forearm, extensive and profound pressure in order to cause the diffusion of the infiltration. Massage the tendon sheaths by profound and rectolinear pressure. Rub the hand and forearm. Use movements of the articulations of the wrists, the elbow, and all the fingers. Terminate the session by a general rubbing massage of the entire member.

Fracture of the fibula.—Disengage the leg gently from the splints or cast and place it upon a long cushion, with the anteroexternal surface facing upwards. Massage the peroneal groups of muscles and the extensor muscles of the toes. At first superficial rubbings are given, followed soon by superficial pressure, but at the end of the third day the same movements are made profound, and kneading is added. Begin by massaging the superior and inferior portions first, as in massage of the foot. Finish by complete massage of the entire region. Movements of the knee, the toes, and the hip are begun early. A Velpeau bandage should be applied in the same way as applied for the sprains, that is, if there is any tendinous relaxation of the articulation.

Fracture of the femur.—The massage should begin after the bone has been consolidated. From time to time the limb may be subjected to a slight palmar rubbing when it is removed from the plaster. This will help dispel the infiltrations. If the fracture does not show any complications three weeks after the fracture massage may be started. In this case the leg is carefully removed from the plaster and placed upon a cushion or folded blanket. The leg should be kept in the position in which it was held by the plaster. Begin by rubbing the section above the fracture with superficial and profound rubbings; these tend to diminish the pain and disperse the infiltrations. The inferior section is then rubbed, that is, the part situated below the fracture, without touching the callus, during the first few sessions. Later proceed with massage practically complete in the leg and by rubbing and superficial pressure of the area of the fracture. Then kneading and percussion for the muscles are added, and profound rubbing and vibrations for the fracture; finally movements of the neighboring articulations—the hip and the knee. But in the meanwhile one must not forget to move the distal articulations—the ankle and the toes.

The movements of the other leg should also be made as a preventive. The war has shown many weird phenomena which have been caused by prolonged immobilization. I have often been puzzled when finding that the fracture of one leg often caused stiffness and even partial ankylosis in the other leg. So, it is better to move the uninjured leg than to encounter disagreeable surprises later. Until the leg has recovered sufficiently to allow the patient to get up, it is best to retain the plaster, but considerably reduced or transfer to a simple maintaining apparatus which is left off as soon as the patient is able to get up.

From this time on the leg is submitted to a complete methodical massage. I begin by rubbing the buttock muscles as soon as the patient is able to be partially turned. In the massage of the buttocks energetic measures are employed, that is, rubbing, profound pressure, kneading with grinding, patting and percussion. After the patient is brought back to his original position I massage the quadriceps, sartorius, and in case of absence of adduction—the adductor muscles. I abstain for some time from massaging the flexor muscles of the leg and the thigh. To massage the anterior surface of the thigh I resort to rubbing, pressure, patting, percussion, vibration, and above all rolling.

Each session is terminated by passive movements; abduction and adduction of the leg, flexion and extension of the leg upon the thigh, the thigh upon the trunk; circumduction and rotation of the coxofemoral articulations. Active movements: above all insist upon those which are absent or badly executed by the patient. Resistance movements.

Fracture of the tibia.—Movements of the hip and articulations of the toes should precede the massage. Rest the leg upon a cushion or folded blanket, massage the muscles of the anteroexternal surface of the leg. The posterior surface of the leg should not be massaged as long as one is not sure that the fracture has not caused a contracture—even partial—of the Achilles tendon or a contracture of the extensors of the foot. At the beginning apply a partial massage rubbing and light pressures, and finish by a complete massage, except rolling which is difficult here.

Passive movements of all the articulations; insist upon movements of the ankle joint; do not forget the outward rotation of the foot. If there is a simple equinous make traction upon the Achilles tendon. Here I use various methods: (1) That which I have indicated in methodical movements. (2) The method of the chest.

The method of the chest consists in the following manipulations: The reclining posture is preferred. The operator assumes a position opposite the plantar surface of the patient's foot. He grasps the heel of the patient with both hands, leaving the tendon free, and places the plantar surface of the patient's foot against his chest. He then executes the following movements simultaneously:

1. Pulling firmly upon the heel which is against the chest.
2. Pushing the plantar surface of the foot with the chest.

Fracture of the inferior extremity of the leg.—When the leg is placed upon a cushion or a folded blanket, the portion of the leg above the fracture is massaged first—rubbing, pressure, and kneading of the fleshy part of the muscle mass. Then the portion below the fracture is massaged—rubbing, pressure and vibration. The articulation is next massaged—bracelet rubbing, digital pressure, which activates the absorption of the exudate and infiltrations in the tendon sheaths. Terminate the session with a general profound rubbing of the entire member, especially the articulation of the foot on the leg. At the same time passive movements are begun; at first, flexion and extension; abduction, adduction, and rotation later; and finally circumduction.

A bandage is of great assistance here. Terminate the treatment by reeducation of the patient's walk as in all cases of fracture of the inferior extremity. This treatment is described in a later section.

Fracture of the metatarsal bones and the toes.—The treatment for fracture of the metatarsal bones and toes does not vary from the massotherapeutic treatment given to the fractures of the fingers and the long bones. As the dimensions here are much smaller, all of the maneuvers here are done with the fingers and not the hand.

MASSAGE FOR STIFFNESS AND ANKYLOSIS.

Stiffness, stiffening, fibrous ankylosis and complete ankylosis are but different phases of the same process. They are as a rule all due to prolonged immobilization. From the massotherapeutic point of view, it is of little importance to differentiate these pathological forms. We will give a general description of the massage which may be applied to all of them. It is understood that each form requires an application more or less vigorous—more or less complete, following the indications of each individual case. As a technical intervention they are all the same except that of a subacute or chronic arthritis.

Stiffness and ankylosis of the shoulder.—Massage the trapezius from below upwards; rubbing, pressures, kneading and percussions. Massage the deltoid; partial at the beginning; rubbing and superficial pressure, followed by complete massage. Use the same process for the massage of the periarticular muscles. Retard the massage of the pectoral muscles until sure that their antagonists are not atrophied. In this case, in order to avoid augmenting the contracture of the pectoral muscles, only massage the atrophied antagonists.

Massage of the articular capsule; profound circular digital pressure, especially of the ligaments of the tendon of the biceps. Massage the triceps, which always have a tendency to hypotonicity. Massage the dorsalis major.

Methodical movements should be given before massage. Follow the session of massage by passive, active and resistance movements. Gymnastics and reeducation are of utmost importance here.

Stiffness and ankylosis of the elbow.—Always begin by methodical movements. Massage the muscles of the arm, except the biceps, which have a tendency to contract. Massage the muscles of the forearm and the articulation as well. Here I utilize superficial and profound circular digital pressure and massage along the ligaments, especially in case of infiltrations, also palmar pressure and profound rubbing. Make use of combinations: profound pressure with one hand and rubbing with the other, executed simultaneously. The one action does away with the swelling and the other conducts the products to the blood stream.

Terminate by passive, active, and resistance movements.

Stiffness and ankylosis of the wrist.—Rubbing and pressure of the forearm to hasten the removal of the infiltrations. Complete massage of the muscles of the forearm. Partial massage of the wrist and hand. Make use of profound pressure for the articulation, and terminate by combating the tenositis of the ligaments and tendons. Passive and active movements should be accompanied by traction on the flexor and extensor tendons.

The methods indicated in the chapter on movements are sufficient in this case. I vary here the process of the "chest" which has been described. The palmar surface of the hand is placed on the chest of the operator, who holds it with one hand and with the other hand he presses the forearm from above downwards, holding it just above the wrist.

In certain cases, when the retraction of the flexor tendons of the fingers is marked, I utilize a method which serves at the same time as a method of exploration. This condition may be present in neuritis of the radial or ulnar nerves, in hemiplegia, or in spasmodic contractures. The process consists in straightening the fingers when the flexion of the hand upon the forearm is at its maximum. First of all the wrist is put in complete flexion. Then the fingers of the patient are grasped and placed in extension. When this is done, the hand of the patient is lifted, grasped by the palmar surface, and swung from above downwards around the horizontal axis of the radiocarpal articulation.

If the tendinous retraction of the flexors of the fingers is not definitely marked one will find that he has brought the articulation back to the normal condition, after a few exercises of this kind. In any case, some gain is made, but if the contracture exists and once the hand is left, the fingers will always remain more or less flexed.

This process serves as a method of exploration for the degree of contracture of the flexors of the fingers. When we forcibly flex the wrist of the patient we can determine if he can straighten his fingers completely, or whether the contracture is accompanied by a partial retraction of the tendons in their course. It is sufficient to lift up the hand of the patient; in the first case the extension will be partially maintained, while in the second it will be completely absent.

Stiffness and ankylosis of the hip.—Apply complete massage to the buttock muscles, complete massage of the quadriceps, including rolling and grinding movements; complete massage of the posterior muscles of the thigh if there is any sign of atrophy, if not abstain from massage, especially at the beginning of the treatment.

As the articulation is deeply placed, it is difficult to reach in its entirety, by massage. The inaccessible parts should be attacked by profound pressure.

Always begin by movements of the articulation. If the ankylosis is complete, it is useless to attempt movements. In case of partial ankylosis methodical movements are indicated. In case of chronic or subacute arthritis, employ passive movements—gently. The treatment is terminated by active and resistance movements.

Stiffness and ankylosis of the knee.—Begin with methodical movements. Complete massage of the quadriceps. Do not massage the posterior muscles of the thigh as long as the tonicity of the quadriceps remains subnormal.

Massage of the articulation, preferable with the two thumbs. Follow the plan which has been indicated for the massage for sprain of the knee—passive, active, and resistance movements. In case of arthritis insist upon massage of the capsule and the lateral ligaments.

Stiffness and ankylosis of the ankle joint.—The methodical massage of the articulation should precede the massage. The treatment is the same as that in the case of a sprained tibiotarsal articulation, except in the first period, where it is necessary to give partial massage, but not in this instance. Give complete massage of the anteroexternal muscle of the leg, the foot and the articulation as well. For the latter I prefer to employ digital pressure, profound and circular. Passive movements in this case are always accompanied by traction of the Achilles tendon, by the chest method which has been described. Terminate the session by large profound rubbing of the entire leg. This is designed to reestablish the circulation of the inferior extremity.

32 RUE DE LIEGE.

Exercise in Acute Infectious Arthritis

By SAMUEL W. BOORSTEIN, M.D., F.A.C.S.,
New York.

The rapid progress of orthopedic surgery, especially during the recent war, has revolutionized many of our old dogmas of exercise in the treatment of diseases. Willems, with the mobilization treatment of knee infections; Rollier with the sun treatment; particularly Sir Robert Jones in his repeated encouragement of the value of occupational therapy; the institution of early motion in fractures and exercises in acute cardiac disease by many authorities, has raised the value of exercises to its deserved appreciation.

A great deal of space is given in the medical literature to this work though the medical schools have not given it proper place in the curriculum.

There are, however, some chronic diseases, or rather acute ones which are allowed to become chronic, where the value and need of exercises and occupational therapy have not been emphasized sufficiently. Among those diseases is the acute infectious arthritis or what the laity calls rheumatism. In this disease the old theories are still followed.

In a previous article (1), published in 1912, reporting the early results of work on arthritis deformans by Dr. G. R. Elliott and myself at the Montefiore Hospital, I stated the following:

"It has been shown that the deformities of arthritis deformans are more marked in the well to do people, because they can afford to remain in bed and be supplied with all the necessities by their servants. The result is that they become bedridden very early. The joints gradually become deformed and flexion is prevailing. The poor patients, on the contrary, have some employment as housework or finding means of existence and, therefore, are in constant motion and thus prevent deformities. The slight trauma produced by the constant maneuvering is not enough to forbid the continuance of daily work."

Since that time I have followed the phase of treatment with great interest. Up to the present time I have found no reason to retract my statement but, on the contrary, am more enthusiastic. The different experiments carried out by myself and the articles published in the literature have added proof to the assumption formerly expressed.

This article is written for the sole purpose of interesting the general practitioner and the laity and thus avoid disabilities, which are not only a drain upon the patient's immediate family, but also on the country at large.

To have a proper and clear idea of the class of cases under consideration, we include that form of arthritis formerly called arthritis deformans and by the English writers called rheumatoid arthritis; at present called acute polyarthritis, which usually terminates in chronic progressive polyarthritis (monoarthritis is of course included).

The laity, as well as the general practitioner of the old school, still designate it by the old preposterous term rheumatism. This alone helps make the patient submit willingly to permanent crippledom.

The technical definition is: A polyarticular affection (monoarticular can be included), beginning either acutely or insidiously, generally involving in a symmetrical manner the distal joints of the fingers and extending to other joints in more or less rapid succession. It usually begins with a rise in temperature (though this may be absent and not noticeable); pain which is the predominant symptom and occasionally swelling.

One should at once take into consideration the age and sex of the person afflicted. Excluding cases where the infection is found in the joint directly, this disease is much more prevalent in women, and in adults. The disease commences most commonly between the ages of twenty and thirty, occasionally even before twenty.

We thus see that the disease is common in a class of people that are by nature, in a modern civilized country, more indisposed to work, more neurotic and more accustomed to visiting and consulting physicians.

The psychology of the patient, i. e., whether she really has the desire to be cured and whether she is anxious to give the physician the proper assistance, plays an important part in the prognosis. It must be borne in mind that many cases are erroneously traced to a slight injury, for which the patient sues for compensation. In these the patient is not willing to exercise during the acute stage, when pain is still present. The present cases of the War Risk Insurance Board demonstrate this only too well.

It is not necessary to dwell on the etiology, as this is beyond the scope of this paper. We may only review briefly the treatment. Besides looking for the source of infection and removing it where possible, the joints are usually put in plaster splints for a short time—(ten days). Then baking, massage, and other measures are instituted. It is just at this stage that the exercises, properly directed, should be begun and followed up for a long time. This prompt commencement of exercises prevents deformities and disabilities.

Pathological changes are as follows:

1. The morbid process begins in the synovial and periarticular tissues, which undergo thickening, with abundant villous proliferation and new formation of bloodvessels. The cartilage, at any rate in the early stages, remains intact.

2. The changes that ensue in the cartilage and in the end bone are to be regarded as secondary.

3. In some cases proliferative changes take place in the bony and cartilaginous structures, giving rise to irregular bony outgrowths at the level of the articulations.

4. The terminal stage is marked by shrinkage of capsule, with obliteration of the joint cavity and ultimately fibrous or even bony union of the articular ends of the bones.

One must also keep in mind the conclusion of Nichols and Richardson, that the infectious agent is usually of a low virulence and these result in a local anemia from endarteritis of more or less obliterating type. This is followed either by proliferated or degenerative changes in all the joint structures, tendons and muscles.

We thus see that in the acute stages the soft parts, namely, the fibrous and synovial capsules, are involved and they tend to form adhesions and cicatrization, and cause the deformities which are so disabling. In many cases of severe infection, the joint cavity is entirely obliterated. The adhesions between the two layers of the synovial membrane are so firm that no force will separate them.

In former years exercise used to be considered distinctly harmful, for the writers believed that exercise tended to increase the adhesions and cause ankylosis. At present the opinion is reversed—that the exercise will prevent adhesions, the increased circulation will cause elimination of toxins.

Willems's observations on acute septic knee can easily be applied here. According to him and all those who have followed his work, "even in purulent arthritis excellent results are obtained by immediate active mobilization." He advises a unilateral or bilateral arthrotomy followed by immediate active motion of the joint, even instructing patient to walk after the temperature has fallen below 100° F. and while the joint still has a large opening.

We will quote a few authorities on the value of exercise in acute arthritis thus showing the modern tendency in these cases:

Lewellyn Jones (8), in his excellent treatise on arthritis deformans states emphatically: "It need hardly be said that the patients must be got out of bed as early as possible and encouraged in every way to use their joints, which otherwise become increasingly stiff. In the chronic cases, regular exercises, proportionate to their power, should be insisted upon. Great firmness is necessary to insure exercises being regularly carried out, as it is by no means easy to convince the patient, when in pain, of the necessity of perseverance in this direction if future crippledom is to be avoided."

Painter, Goldthwaite and Osgood (7), who have done so much original work on arthritis writing in connection with infectious arthritis, state: "Passive and active manipulation are frequently required, even at the cost of considerable suffering to the patient, before the desired result is obtained. . . . Patients are all likely to become more or less neurasthenics and require constant incentive in order that the best results may be secured. A great deal of the success of treatment depends upon the cooperation of the patient in every detail."

Sir Robert Jones (10), lauding occupational therapy in injured soldiers, says, and his words can be paraphrased easily and we can agree with him that "She would cheerfully spend the morning grasping a big duster and cleaning windows. Her mind is set on the dirt she has to remove, not on the fact that her maimed hand is repeatedly taking hold of and letting go the duster. If the patient is in an atmosphere of work, she soon recovers some hold of herself and wishes to do something, even to make beds for patients."

In a recent article on acute polyarthritis (4), I have stated emphatically, "Active exercises are of great value. As soon as inflammation begins to subside, have the patient himself go through the normal range of motion of the joint two or three times a day and perform each motion about five times."

Even if in spite of proper treatment some ankylosis or deformity becomes inevitable, the limbs are in a better position and the muscles are in better tone and can perform a great many more normal functions.

The only questions at present are: 1. When to begin the exercises. 2. How to carry out the exercises. 3. Forms of exercises. 4. Guarding against overuse.

WHEN TO BEGIN THE EXERCISES.

Authorities agree that active exercises are the only ones that can help restore the person to proper health. The patient must be encouraged to do the exercises himself, do them often and do them regularly. The physician, with all his persuasive power, is not always able to control the patient and get the proper cooperation. As stated, this disease is common among women between the ages of twenty and thirty. It is well known that women at that age want a great deal of sympathy when they are sick. It can almost be said of modern women that they take pride in being sick.

The desire for independence enters frequently in connection with this disease. In spite of the general theory of woman's desire for independence, the orthopedic surgeons, the neurologists and social service workers are aware more than others that if a woman can find any pretext for not working, she does not work.

If the case is the basis for a legal controversy as suing for damages because of an accident or under the workmen's compensation or fighting a will, the slightest deformities are usually exaggerated to the extreme and some of those assumed.

In a previous article (2), in 1912, I stated: "Exercises must be insisted upon and should be begun as soon as signs of acute inflammation have subsided. Active and passive movements are of great advantage. It is quite hard to induce the patient to do the exercises which really cause pain, but the physician must use his utmost influence to persuade his patients to continue it regularly. Most of them are neurotic and with these such advice is easier given than followed. With older patients, specially women, this persuasion is more difficult."

In the ten years that have passed since the writing of this article my belief in these conclusions has been strengthened.

The active exercises should be begun while the patient is still in bed and while the joints are still inflamed, but of course the patient should be encouraged to use them himself only for a few motions.

HOW TO CARRY OUT THE EXERCISES.

I wish to emphasize here that in spite of the strides made in this disease where the source of infection is carefully sought and removed, also the excellent work with baking, massage, etc., our duties as teachers have not been fulfilled unless the laity understand definitely that many of these cases can be improved early or at least the marked disability and deformities may be prevented.

The patient should help and continue to help and not leave the active work towards her recovery entirely to the masseuse, nor should she depend upon the much advertised but valueless springs and leave to the Almighty, who gave such a wonderful spring, to do the work Himself. "There is no balm in Gilead" may be used as an argument against those springs.

The motions should be begun while the acute inflammation is beginning to subside and the patient should do them herself. These motions will be found to be less and less provocative of pain and productive of a greater range of motion as time goes on. It is at this period that the teacher of occupational therapy should be employed, so that the exercises may take some useful and interesting form while the extent is under proper control.

We have not yet reached the stage where it is customary for an orthopedic surgeon to send a teacher of occupational therapy regularly with orders as we now send a masseuse. In an institution, teachers are already obtainable but are not yet available for private cases.

Many exercises can be performed in the house without a teacher, such as washing dishes, cleaning glassware (the care that she has to take of the valuable glass will encourage her to use the hands properly).

As soon as the patients can sit up in the chair, the extent of occupations can be increased; as soon as she can walk, the question of housework should be taken up. Among the poor this does not come up. As quickly as possible, she washes the dishes, sweeps the floor and prepares the meals for her poor and unfortunate husband. She only asks the physician: "Am I permitted to wet my hands?" I cannot trace exactly where the idea originated that it is forbidden to moisten the hands. At present hot water is so easily obtainable that it is hardly probable that a woman would wash greasy dishes with cold water. Why could she keep her hands in hot water for a treatment or put a hot water bottle to her hands and not wash the dishes?

Of course with the rich class housework is out of the question. They are finally convinced that God has given them delicate hands to wear rings and loll in rocking chairs, and even the supreme duty of keeping her infant on her hands she leaves to a maid or a nurse.

This is not a lecture on economics and thus it must be shortened. It is, however, a plea for more natural exercises and work in this only too common affliction; and it is just as much of a hospital question as an economic. Orthopedic surgeons who have to do with chronic cases know too well that these cases are a burden in the acute hospitals, a hardship in the hospitals for chronic diseases and certainly a struggle for the family. One patient with chronic arthritis is a great burden to the family and will often ruin them completely, besides neglecting her husband and children.

Of course active exercises can best be performed under the guidance of occupational therapy teachers, who can at first select occupations to be used by the patients while in bed and later on some others, when the patients are able to leave their beds.

FORMS OF EXERCISES IN OCCUPATIONAL THERAPY.

We must at first choose the line of work that will help that particular deformity, to carry out this work intelligently.

I undertook, in conjunction with Miss Johnson, lecturer at Teachers' College, to select a distinct group of work suitable for these cases. We have always to keep in mind not to give them occupations that may increase the tendency to deformity.

We will take up each motion found in normal people and give them occupation suitable for that.

I—UPPER EXTREMITIES.

(1) Finger flexion and extension. We abandoned sewing, knitting and crocheting with fine needle, as this is tedious and causes flexion of the fingers. Needle work uses only the small muscles. We picked out clay modeling. That is preferable to any other occupation, in cases where there is pain, stiffness and limited motion. The plastic yielding quality of the soft, slightly moist medium (clay) helps to reduce stiffness and increases motion. Clay modeling is especially recommended as an initial step and the outfit is very cheap. It can easily be adopted and adjusted as far as holding the chisel. The needle in needle work is fixed and tires out the muscles while the clay can be changed in different positions. We use Monolith. Typewriting can also be used.

(2) Wrist flexion and extension (for pronation and supination see elbow motion).
- (a) Clay modeling.
- (b) Knitting and ring knitting.
- (c) Block printing (especially good for extension).

(3) Elbow flexion, extension, pronation and supination.
- (a) Weaving a hand loom.
- (b) Making hooked rugs.
- (c) Knotting and netting.
- (d) Braiding strips for rugs.
- (e) Working on large pieces of needle work.
- (f) Carpentry—fret saw and hand carving.
- (g) Sand papering, decorating, painting, shellacking.

(4) Shoulder movements: Adduction, abduction, flexion, extension, rotation outward and rotation inward, adduction and abduction on the level of the shoulder, etc.
- (a) Most of those assigned to elbow and wrist.
- (b) Weaving on a large loom.
- (c) Carving.
- (d) Carpentry.

II—LOWER EXTREMITIES.

A. Foot: 1. Dorsal flexion.
  - (a) Sewing machine (foot power).
  - (b) Foot loom.
  - (c) Jig saw.

2. Plantar flexion.
  - (a) Sewing machine (foot power).
  - (b) Foot loom.
  - (c) Jig saw.

3. Inversion or abduction.
4. Eversion or abduction.

(At present we have no machines to suit these.)

B. Knee. 1. Flexion:
  - (a) Sewing machine.
  - (b) Foot loom.
  - (c) Jig saw (to a slight degree).

2. Extension—Potters' Wheel.

C. Hip. 1. Flexion:
  - (a) Foot loom.
  - (b) Jig saw (to a slight degree).

2. Extension—(a) Jig saw (to a slight degree).
3. Adduction—(a) Foot loom (particularly with 4 and 6 treadles).
4. Abduction—(a) Foot loom (particularly with 4 and 6 treadles).
5. Inward rotation.
6. Outward rotation.

ABUSE OF EXERCISES.

However, one must not allow the pendulum to swing too much to the other side, and, instead of prolonged rest previously prescribed and practised, use continuous vigorous and frequent exercises. It is a well known fact that repeated traumas will affect the type of deformities which will develop.

Swaim (12) expresses the symptoms of overuse as follows: "What are the symptoms and signs of overuse of a joint? They have pain, tenderness, swelling and stiffness; in other words, inflammation. The important signs are swelling and continued pain. A damaged joint will always be painful, tender and stiff after unaccustomed use, but it will not swell if not overused, and the pain will subside quickly with rest. Consequently, one of the best guides is lasting pain and swelling. Soreness and transitory pain is not a contraindication to use, but pain and aching lasting for several hours and not ceasing, with the stopping of work, show that inflammation had been produced and harm done."

It is a wise policy to see that the exercises should be given every day for about five or ten minutes and later on increased to longer periods and perhaps twice a day. Lessons in control are better given by occupation than by gymnastics or exercises.

CONCLUSIONS.

1. Exercises are of great help in improving joint conditions in acute infectious arthritis, though they do not cure the disease.

2. Total abstinence from work and leading an inactive life are dangerous and frequently a marked factor towards producing permanent crippling.

3. The patient must be out of bed as early as possible and encouraged in every way to use the joints, which otherwise become increasingly stiff.

4. As soon as the inflammation begins to subside, have the patient himself go through the normal range of motion of the joint.

5. By mobilization, the joints are kept supple, adhesions are prevented from forming and the elasticity and tone of the muscles are preserved and their wasting is minimized.

6. Occupational therapy is preferable to exercises, as it assures some interest of the patient.
7. Active exercises, especially occupational, should be begun very early, while redness and swelling still exist.
8. By using occupational therapy, the exercises will take some useful as well as interesting form.
9. Separate occupations can be chosen for the exercising of individual joints.
10. Lasting pain and swelling after exercises show that the joint has been overused and this should be guarded against.
11. The exercises of occupational therapy are only important adjuvants to the established treatments of infectious arthritis.

REPORTS OF CASES.

I will report a few interesting cases to illustrate certain phases of the effect of exercises:

CASE I.—H. M, a young man of twenty-seven, when he came under my observation in 1910 in Montefiore Hospital, with an acute attack involving all joints, a helpless invalid unable to use his hands even to feed himself. The attack came on a few weeks after his graduation from the College of the City of New York. Patient intended to study law and felt greatly grieved that he had to interrupt his studies. After making rounds of the different institutions for a year and a half, he came under my care.

Putting him under the treatments generally used, the inflammation subsided slightly and he began exercises in two weeks. Within three weeks he no longer had to be fed. He himself worked, using his joints and invented new exercises (at that time we knew nothing about occupational therapy), and improvements were marked. Within three months he was able to shave himself and within six months he left the hospital. He resumed his studies, and went through the law school and became a useful (?) attorney.

Comment.—The will power of this patient and the desire to follow his studies caused him to submit willingly to the pain, perform the exercises and correct the deformities.

REFUSAL TO DO EXERCISES.

CASE II.—S. F., female, aged twenty-nine, married, extremely neurotic, quarrelsome and cranky. Had influenza in 1918 and after that became supersensitive and exaggerated any pain she had. Complained of pain in the finger joints. I could not find marked arthritis but attributed the pain to the after effects of influenza. She had formerly been employed in a hospital for incurables, where she saw many arthritic cases. She thus considered, without any foundation, her arthritis incurable, though it was, a very mild case and a good prognosis could be expected. Baking and massage were prescribed, housework was also strongly advised, both to prevent deformities, hasten recovery and also on account of the extreme neurotic temperament. She, however, refused to do housework and even neglected her children and was busy all day with the baking and massage as is habitual with neurotic patients. She eventually, however, resorted to calisthenic exercises on the advice of her female friends, to reduce the corpulency induced by her sedentary life. I considered her too neurotic to be treated by an orthopedic surgeon and discharged her. A few years later I heard that, though her disease had not progressed, she still considered herself an arthritis case and led an inactive life which led to family hardship.

Comment.—This case demonstrates the unwillingness of some women to do exercises, even when the case is mild. Fortunately, the calisthenic exercises taken for beautifying purposes were the means for a beneficial end.

USE OF EXERCISES.

CASE III.—O. F., female, single, aged twenty-four. While a pupil nurse, fell and injured her left knee, was confined to bed a few days during which time she also suffered from a sore throat. The knee became swollen and painful. Had to give up her training and returned home on the advice of her physicians, to stay in bed for a few months. The knee did not improve. The swelling and pain increased and the patient could not put any weight on the knee. As she was very poor and had no one to take care of her, she was admitted to a home for incurables at the age of twenty-four. She was there for a year and a half. By accident she was seen there by one of the ladies of the social service department of Fordham Hospital, who felt somewhat touched by seeing such a young woman become a cripple. She therefore had her transferred to Fordham Hospital and placed her under my care. The examination showed a distinct infectious arthritis of the knee. The knee was placed in a plaster cast for ten days, then baking and massage started. The sight of the nurses in their uniforms aroused in the young woman the desire of again becoming a nurse and she finally picked up courage and asked me whether she would be able to go back to training. Though I hesitated to encourage her, I told her that she might be able to return in a year. She decided then to help the nurses to make beds, etc., while walking with a cane. She improved very rapidly so that within two months she was permitted to go part of the day without a cast while doing the ward work.

A dance given by the nurses was another stimulus to the young lady to increase her active exercises, and she no doubt reminded herself of the dances that she attended while a pupil nurse. Within three months she asked permission to leave the hospital to go to a convalescent home for two weeks. She asked me privately (with a flush in her cheeks) whether she could dance while there, which I gladly permitted.

She returned from there in better health and has made a perfect recovery in one month. She has now returned to the training school to continue her studies.

Comment.—The great desire to become independent has forced her to do active exercises and the ward work, which she was so anxious to do, caused her to perform all the necessary exercises without any complaint. The rapid recovery proves the great value of occupational therapy—housework being the therapy used in this case.

A bibliography will appear in the author's reprints.

Results of Exercise for the Correction of Postural Defects

By ROBERT JAY COOK, M.D.,
New Haven, Conn.,
Assistant Professor of Surgery, Yale Medical School.

The purpose of this paper is to call attention to the value of correcting postural defects, and to show by analytical tables just what can be accomplished by systematic exercises given under supervision.

The common postural defects found among men entering Yale are round shoulders, increased anteroposterior curvature as kyphosis or round back, lordosis or hollow back, scoliosis either postural or structural, flat chest, prominent abdomen, and weak feet which term includes the several types of foot strain and foot abnormalities.

Dr. L. T. Brown (1) worked a classification for the students of Harvard University which most institutions have followed. In his paper Dr. Brown classifies the postural defects found as a whole and gives them a single rating of A B C or D. This rating is a composite of their trunk and head posture combined with an evaluation of the function of their feet. It has seemed to the writer that this classification, i. e., combining trunk and feet with a single body rating was too complicated and that it would be more advantageous in considering posture if the classification should rest upon the defects of the trunk, and then classify the defects of the feet separately.

In a paper entitled a Report of the Orthopedic Examination of 1,393 Freshmen at Yale University, I called attention to the fact that but twenty-five per cent. of these men had a normal spinal curvature, that over fifty per cent. had some scoliosis, and that over fifty-five per cent. had an increased anteroposterior curvature. The chest was flat in fifty-six per cent. of cases and the abdomen was prominent beyond the normal in forty-two per cent. of men. Without an analysis of a large group of men it would be difficult to realize that poor posture is so common. This year with a total analysis of over 2,200 men we find that our statistics are practically the same. When it is considered that these defects are found in men who have just completed their high school or preparatory school we become impressed with its seriousness. Living in a period when the cry is for preventive medicine one wonders why we wait until the individual is developed before an attempt is made to correct defects of posture which yield to corrective therapy so much more readily in the child than in the adult. It seems certain that these defects are forming during both the graded school and high school life of the child, and if some corrective therapy were instituted in schools at this period the poor posture found so commonly among adults could be avoided. In other words, it would be desirable, in addition to the usual athletic sports of school life, to require instruction in corrective gymnastics in order to prevent the development of round shoulders, round back and the too common spinal curvature. The advantage of good posture lies not alone in appearance but in general health, general efficiency, and improved mental capacity. Whether the cause of the poor posture of the child lies in malnutrition, disease, overgrowth, or overwork he would benefit by being under trained supervision to assure the development of his body along lines which are generally recognized as normal.

The study of postural defects has been carried on for three years at Yale. During the first year we attempted to carry on the corrective work in the general gymnasium but the amount of work required in this type of corrective gymnastics proved too much and we found at the end of the year that but little had been accomplished in the correction of postural defects though the man had profited much by the exercise and in most cases had considerably strengthened himself. Following this trial we set aside a room in the gymnasium to be used only for the correction of postural defects and placed the work in charge of men qualified in corrective gymnastics. It is the study of these cases upon which this report is based.

It is interesting to note the posture of the men entering from the various types of preparatory schools. In general those entering from military academies lead, the boys from the private preparatory schools came next, although following the war when men entered who had been under military instruction in high schools the year or two previously they outrated the private preparatory school boy in bodily posture. Following these came the group entering from high school. Of course exceptions to the rule are found in all groups. The easier life of the boy who can afford to go to a private school as against the public school boy who often must work to defray part of his expenses may to some extent explain the difference. Upon talking with the boys from both private schools and public schools we find that only occasionally has effort been directed to overcoming their postural defects, and we think that it would be possible for both types of institutions to give more attention to the posture of their students.

For the past two years we have carried on our work by dividing the men into groups of ten or twelve, and have given the correctional work from Thanksgiving to Easter, a period of fifteen weeks. The men are stripped so that the body can be seen at all times, both by the instructor and by the man himself in the mirror. The general plan of the exercises has been to stretch out the contracted muscles, to obtain greater flexibility of the thorax and greater freedom of the shoulder girdle, and then to increase the tone of the trunk muscles. In some cases of scoliosis it was necessary to add asymmetrical exercises—in others it was necessary to use manual stretching especially in resistant cases of round back and round shoulders.

In the work of the past two years we have the complete records of over five hundred men and in the analysis of these I have grouped them according to postural defects.

It has been interesting to note that the man who had scoliosis combined with increase in the anteroposterior curvature improved both conditions even though his exercises were directed mainly at overcoming the major one. In fact, the man who corrected any defect usually corrected all in about the same proportion. Rarely did a case show no improvement.

The main reason for presenting this work is to show just what can be accomplished among school boys by corrective work, and to urge those who are interested in the field to check up their results since it is evident from a study of the tables presented herewith that many cases listed as partial correction could be completely corrected by a little more individual work, even though during the period of correction the improvement of the posture of the man seemed satisfactory.

TABLE I.—CORRECTIVE GYM.—ANTEROPOSTERIOR CURVES.

Correction	Complete		Partial			None		Increase	
KYPHOLORDOSIS—									
Deg	*Cases*	*Deg.*	*to Deg.*	*Cases*	*Deg.*	*Cases*	*Deg.*	*to Deg.*	*Cases*
1	44	2	1	77	1	46	0	2	3
2	17	3	2	18	2	34	1	2	3
3	5	3	1	18	3	5	2	3	1
		4	2	3					
	66			116		85			7
KYPHOSIS—									
1	32	2	1	4	3	2	1	2	2
2	19	3	2	1	2	23			
3	2	3	1	3	1	15			
	53			8		40			2

We have grouped the increase in the anteroposterior curve in groups numbered respectively 1, 2, 3, 4 according to the increase in the curvature, in the same manner we have grouped round shoulders, while the carrying of the neck and head forward has been grouped according to degree from the perpendicular. Scoliosis has been measured from the height of the apex of the curve to the base line drawn between the spinous process of the seventh cervical vertebra and the spine of the sacrum.

In Table I dealing with accentuation of the anteroposterior curvature of the spine we found that we had been able to correct completely sixty-six cases of kypholordosis and fifty-three cases of kyphosis, to correct partially 116 cases of kypholordosis and eight cases of kyphosis. There were eighty-five cases of kypholordosis and forty cases of kyphosis in which no correction was made and nine cases in which the defect became worse. It has been our experience that the correction of round back is the most difficult part of the problem in the correction of postural defects among this group of men. Among these students it is decidedly more resistant to corrective exercise than is round shoulders or postural scoliosis.

TABLE II—NECK FORWARD—MEASURED IN DEGREES FROM THE PERPENDICULAR.

Our Table II deals with the carrying of the neck and head too far forward.

The correction of this defect has been quite satisfactory. In many cases it is associated with kyphosis or round back, the correction of which helps in the correction of the carrying angle of the neck. The carrying of the neck too far forward can be corrected without correcting the associated kyphosis in which case the kyphosis is concealed largely but we cannot too strongly urge that the correction of the round back should be attempted as well as the correction of the carrying angle of the neck when the two are coexistent. In this group we were able to correct completely 212 cases, to partially correct 145 cases, while seventy-three cases showed no improvement, and eight cases showed an increase in the carrying angle of the neck.

Our results in the correction of round shoulders show that 168 cases were completely corrected, 189 were partially corrected, ninety cases showed no improvement, and seven showed an increase in the defect.

In part our failures seem traceable to the attitude of the student who does not always enter fully into the spirit of the work, and part may be due to pushing too rapidly the man who has outgrown his physical strength. In the latter case it is probable that his work should have been of a much lighter character.

Reviewing our cases of postural scoliosis we find 101 cases completely corrected, these cases varying from a quarter to one inch, ninety-four were partially corrected, sixty-two cases showed no correction, and twenty-one showed an increase of the curvature.

For a detailed study of the postural defects found in the freshmen at Yale I refer to my former article (2).

These defects of posture found among young men do not tend to disappear without corrective work but they can be overcome by such, some by the nature and severity of the defect requiring a longer period than others. Since they are formed long before the student enters college it is certain that much could be accomplished in the way of prevention, or, when found, in the way of correction if suitable supervision was given to the children of the grade and high schools or their equivalents the boys' school, the girls' school and the preparatory schools. The question is often raised as to whether this correction is permanent or temporary. We have reexamined in the past fall those men who were given correctional work the preceding year and in these cases we can say that the improvement has remained.

Contracted Achilles Tendon*

By A. GOTTLIEB, M.D.,
Los Angeles, Cal.

Achilles tendon contracture as an entity is of rare occurrence but as a misnomer for a contracture of the calf group muscles it forms a condition with various symptoms and signs, which depend upon the underlying etiology and upon the loss in the range of dorsal flexion of the foot.

The normal range of ankle motion is between 70 to 80°, of which plantar flexion is 55 to 60° and dorsal flexion 15 to 20° from the right angled position. The loss of ability to actively and passively dorsiflex the foot to the given range is a condition which we encounter whenever the calf muscles are permanently contracted.

ETIOLOGY.

No age is exempt. It may occur intrauterine, either as a congenital deformity of inheritance or as a developmental defect after conception of a normal fetus has taken place; or it may develop postnatal, ninety-six per cent. of all cases do, from trauma, constitutional diseases, inflammations of the ankle joint, the calf muscles or the Achilles tendon and as a static compensatory contracture.

MODE OF DEVELOPMENT OF THE ACQUIRED TYPES.

1. An injury may cause a traumatic arthritis of the ankle joint with pain and rigidity. To guard against pain, the patient restricts dorsal flexion to a minimum; he rests the foot or walks, if able to, with the foot in plantar flexion. This position allows the origin and insertion of the muscles of the calf to be approached; they undergo shrinkage and contracture, while their opponents, the anterior leg muscles, lengthen and atrophy from disuse.

Injury may result in a fracture of the lower end of the tibia, fibula, or both, without or with joint involvement. If the latter occurs, we have a repetition of the above condition, only more severe, while in fracture without traumatic arthritis we may have to contend with a contracted calf because of the long continued immobilization in splints with the foot in right or obtuse angled position.

Tearing and contusing the muscles may occur in trauma and lead to contracture because passive stretching causes pain and is therefore not practised. Instead of that the leg is strapped or immobilized with the foot in plantar flexion to relieve the tension upon the torn tissues.

Here may be classed the wounds which result from gunshot, shrapnel, knives, deep burns, or other similar conditions. The skin, cellular tissue, muscles, and tendons may be involved in the process and the contractures which follow are in severity in direct proportion to the extent of the injury to the tissues and to the loss of their substance. The contractures are the sequence of the shrinkage of the fibrous scar.

2. As a secondary manifestation in a bedridden patient with a constitutional disease, the contracture may develop. The bed covers press upon and hold the feet in plantar position and if no preventive measures are taken against this damaging influence, the plantar position persists and becomes a permanent one.

Diseases which directly are likely to produce calf muscle contracture in virtue of their pathology are gout, chronic arthritides and other diseases commonly known by the misname chronic rheumatism.

The pathological changes which they produce are similar in character: the ankle joint becomes thickened, its movements restricted, its position-plantar flexion and its controlling muscles partly atrophied, the anterior group more that the posterior which undergoes compensatory shortening and contracts by taking up the slack in the muscles and tendons as it occurs in paralytic conditions to be described below.

---

*Read before the Harbor Branch of the Los Angeles County Medical Society.

Under this heading may be classed the pathological affections of the central nervous system which leave the leg muscles into a spastic or paralytic state depending upon the effect produced, i. e., muscular spasticity or flaccidity. The contractures to follow are known as neurological contractures.

The spastic type is traced back to a direct irritation of the central nervous system and is characterized by an increased tonus of the calf muscles which, although allowing passive stretching, will snap back into their contracted position as soon as the force is released. Spasticity we find after various brain injuries and after brain lesions such as hydrocephalus, porencephalus, brain tumors, sclerosis, syphilis and meningeal and cerebral hemorrhages. Not only cerebral but certain affections of the spinal cord will lead to flexion contractures as well; these are: multiple and disseminated sclerosis, spastic spinal paralysis, syringomyelia and hysteria of long standing.

The paralytic form originates from the injury to the motor nerve apparatus either at the centre or at the periphery. Central paralyses are in most cases the result of spinal cord pathology; cerebral lesions very rarely produce flaccid paralysis. The cord lesions are: Compression myelitis, late stage of tabes dorsalis, spina bifida, progressive muscular atrophy, intoxications from lead and other chemical poisons, chronic spinal meningitis with destruction of the nerve roots, and, last but not least of all, poliomyelitis. In comparison with all the various causes, poliomyelitis overweighs them all in the production of the flaccid type of paralysis with the resulting calf muscle contracture.

The development of the paralytic contractures can be understood on the basis of the antagonistic mechanical theory of Seelenmüller, which, applied in this instance, reads as follows: In all cases of paralysis of the anterior muscle group, voluntary attempt of motion, as dictated by the brain, will result in the transmission of the impulse to the posterior group only, because its nerve conduction is not inhibited. Only the nonparalyzed antagonists will contract and place the foot in the corresponding plantar flexed position. In this position the foot must persist because the paralyzed muscles are unable to counteract the contracted antagonists. Every attempt at motion produces the same effect until these continuous muscular contractions leave the muscles in a lasting spastic contraction. Serious damage to the structure and function of the muscles results from this continuous spasm, eventually causing them to shrink and contract permanently. The mechanical element of this theory is the weight of the foot when walking or recumbent. The weight forces the foot into plantar flexion and augments the above named cause.

3. Acute and chronic inflammations of the ankle joint may lead to the defect in question. The acute arthritis may be caused by an infection through an open wound or the hemotogenous route in infectious diseases, like measles, scarlet fever, gonorrhea, typhoid fever, and others. The chronic, deforming and destructive, arthritides are principally of tuberculous or luetic origin.

Muscular inflammation of the calf group of remote or even unknown origin, besides trauma, comes under consideration. Short lasting myositidis will undergo resolution, while conditions of long standing will lead to degenerative changes within the muscle tissues, will produce disturbance of motion in the dorsal direction and finally lead to contracture of the calf. To these affections may be counted: myositis fibrosa, traumatic and infectious myositis and myositis ossificans.

The tendon Achilles is also susceptible to inflammations which may produce adhesions to the skin, tendon sheaths or to the tibia.

4. The habitual wearing of shoes with heels of at least two inches high produces in the wearer, among other anatomic readjustments, a compensatory contracture of the calf muscles. The foot is permanently held in plantar flexion within the shoe. The origin and insertion of the gastrocnemius and soleus are approached and the muscles thus relaxed. The slack which forms in the muscles will be taken up; they will shrink and contract permanently to an extent directly proportional to the height of the heel worn. This transformation will result into a socalled Schaffer's foot.

TREATMENT.

From the discussion of the etiology may be deduced that the acquired deformity can easily be prevented. Whatever the lesion of the lower extremity be, traumatic or inflammatory, local or remote in origin, the foot must be retained in dorsal flexion in the course of treatment in the acute stage. This pertains to long recumbency and to diseases of the nervous system as well. The Schaffer foot, however, can only be prevented by eliminating the stylish high heeled shoe of today. With these precautions and with the employment of prophylactic physiotherapy whenever indicated in the treatment of the acute condition, nearly all these acquired contractures of the calf muscles could be abolished.

The actual treatment of mild cases, similar to the Schaffer foot, lend themselves to cures by the conservative methods. This consists in the application of physical modalities which are able to produce superficial and deep local hyperemia and to effect a softening of the organized fibrous scar and contracted tissues. Such stimulating physical modalities are: convective heat and incandescent light and heat, for superficial hyperemia, and diathermy and the negative galvanic ionization for through and through heating and dissolving effects. These remedies are preparatory to massage, vibration, stretching and manipulations which follow. Besides these, active and passive exercises must be executed voluntarily by the patient. Among these the most efficient are:

1. The patient is standing at arm length from the wall. The arms are outstretched and touch the wall with the palms at about the height of the shoulders. The entire foot resting on the ground, the patient bends forward in the ankle joints only. Gradually the patient may place the feet further away from the wall, thus increasing the dorsal flexion of the foot when the body falls forward.

2. The patient is standing on the heels with the toes elevated on a wooden block. In this position the body bends forward in the ankle joints until stretching pull is felt in the calves.

3. The patient walks on the heels with the toes raised.

4. Dorsal flexion of the foot by forcibly pulling

each end of a tape placed under the metatarsus. The knee must be held extended in this passive stretching.

If high heels are worn, they must be lowered gradually, because a sudden change cannot be borne by any patient.

Conditions which do not yield to this conservative treatment or those in which it is obvious that nothing short of operation will overcome the deformity, operative procedures must be selected according to indications, i. e., to free adhesions, dissect away old scars, transplant muscles, elongate the tendons or forcibly stretch the shortened muscles under general anesthesia.

Whatever operation be performed, aftertreatment, physical, and mechanical, must be resorted to to guard against recurrence and to restore normal foot function.

The Diagnosis and Treatment of Minor Injuries to the Lumbar Spine and Sacroiliac Joints

By MORRIS B. COOPERMAN, M.D.,

Philadelphia, Pa.,

Instructor in Orthopedic Surgery, University of Pennsylvania Post-Graduate Medical School.

Minor injuries to the lower part of the back are of frequent occurrence. Many of them occur among the working class. An early diagnosis and the application of appropriate treatment are greatly to be desired to reduce the tremendous cost in money and wastage in time that a large percentage of these cases entail. From personal observation of a number of chronically injured backs, and from studies made by Sever, Wallace, Cofield and others, it appears that the period of incapacity from which these patients suffer is entirely too high. When patients are disabled from five to seventeen months on account of injury to the lower back, some of them of a minor nature, it is evident that either a proper diagnosis had not been made or the treatment had not been adequate.

I believe that the trouble lies in the haphazard method of grouping all these injuries into the category of sprains with no attempt at accurate or scientific diagnosis. In truth, no other part of the body has been the subject of so much unskilled and random diagnosis. The pathological condition manifestly present seldom seems to attract attention. As a matter of fact, many of these cases are exceedingly puzzling in their clinical manifestations. It is a fascinating study to trace an inadequately defined pain to its true source.

In a study of disturbances of the lumbar spine and sacroiliac joints, it has been customary to divide them into the following groups: static, toxic, and traumatic. It is with the latter group that we are most concerned. The traumatic group is further subdivided into acute and chronic types. The point must not be lost sight of, however, that a static or an arthritic back, being traumatized, will give rise to more serious symptoms than a normal back sustaining the same degree of trauma. Furthermore, there may be involvement of the spinal cord or large nerve trunks in this region which will produce a train of symptoms obscuring the injury to the spine itself. The anatomical peculiarities of this region must be remembered, because without a knowledge of the muscles, joints, and nerves, we will often be misled in interpreting what is actually present. It is also well to remember that there are wide variations in response to injury in different individuals. For instance, two men may be injured in a similar manner, viz., a slight twist of the spine. One will get well with little or no treatment, while the other has a long period of disability even with adequate treatment.

TYPES OF BACK INJURIES.

Depending upon the degree of violence, injuries to the back may be divided into the following groups:

Group 1.—Mild or trivial injuries. These are the contusions, strains of ligaments, muscles and aponeuroses and slight twists of the spine, resulting from blows directly upon the back, by falling objects, by lifting heavy objects or in falls from a height. The symptoms are local pain and some stiffness which may subside in the course of a few days.

Group 2.—Moderately severe injuries such as sprains, severe contusions, subluxation of vertebræ or sacroiliacs, fractures of spinous processes, transverse processes, or compression fractures of the bodies of the vertebræ without displacements and without cord involvement. The x ray is of paramount importance in diagnosing these cases. The symptoms are local pain and tenderness. Sometimes there will be swelling and discoloration. The muscles are rigid and joint movements are markedly limited.

Group 3.—Severe injuries to the spine. In these cases we have fractures or fracture dislocations of the vertebræ with cord involvement. As a rule their diagnosis offers no difficulty, because the symptoms point to serious lesions of the cord or nerves. In this type there may be the paraplegias, bladder and rectal symptoms. The x ray determines the extent of bone injury but neurological examination is essential to determine the degree of cord and nerve involvement. Spondylolisthesis may be considered in this group. It is a dislocation of the lumbosacral junction between the fourth and fifth lumbar vertebræ, whereby the lumbar vertebral column slides forward on the pelvic inlet. Injury may precipitate this condition. It is recognized by marked lumbar lordosis, diminution of the pelvic inclination and vertebral shortening of the trunk. On rectal or vaginal examination, there is a marked angularity between sacrum and lumbar vertebræ. An x ray examination clinches the diagnosis.

Group 4.—Injuries to those suffering from chronic spondylitis. In these cases a knowledge of the patient's previous condition is essential. Chronic spondylitis, hypertrophic osteoarthritis of the spine or chronic rheumatism of the back is a progressive disease, most common in men past middle life. Traumatism will, in many instances, aggravate the chronic inflammatory process in the vertebral joints. A slight blow upon the back or a fall associated with a twist of the spine or the lifting of heavy objects will set up a train of symptoms which may be quite severe. Chronicity seems to be characteristic of this disease. The back, naturally stiff and irritable, will become more irritable. Jars, walking on uneven surfaces, sudden movements or acts, such as coughing or sneezing, will produce pain, sharp and cutting in character, usually on one side of the lumbar spine, if the injury has been unilateral. Sometimes the sacroiliac joints are also involved and in such instances we have the referred pain down the back of the thigh and leg, viz., symptomatic sciatica. An examination will show flattening of the lumbar region, boarding or muscular rigidity and marked limitation of movement. The gluteal muscles may be atrophied and tonic spasm may be elicited in the hamstrings of the injured side. X ray examination will usually demonstrate lipping of the vertebral bodies, osteophytic outgrowth or bridging of the vertebræ or arthritic changes in the sacroiliacs.

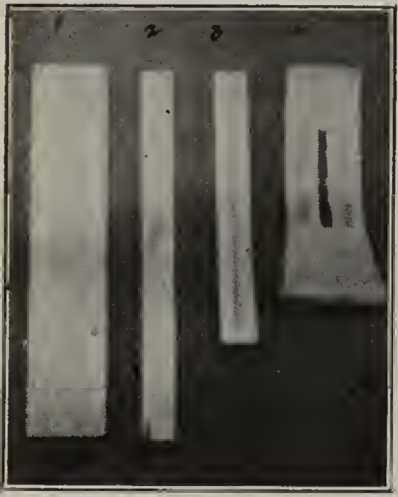

FIG. 1.—Splints. 1. Splint board as it is obtained from the surgical supply house. 2. Single strip cut from large piece. 3. Reinforced strip held together by adhesive already moulded. 4. Splint assembled.

Group 5.—Chronic traumatic spondylitis of the lumbar spine and traumatic flat backs. In the latter there is usually an associated osteoarthritis in either one or both sacroiliac joints. This differs from group 4 in that the patient was normal prior to the injury. In this group we must also consider that a tuberculous infection may follow traumatism. The history of the patient usually is as follows: Following a mild or moderately severe injury of the spine, they begin to suffer from pain, weakness, and stiffness. These symptoms gradually become worse and produce chronic invalidism. In some patients there develops a round kyphosis involving several vertebræ. This is a nontuberculous rarifying osteitis of the vertebral bodies first described by Kummell in 1895. The softening and collapse of the bodies give rise to deformities not unlike Pott's disease. In other cases a different clinical picture is observed.

The traumatic flat backs are brought about by chronic strain upon the lumbosacral articulation or unilateral sacroiliac joint strain. In these cases the lumbar spine has lost its anterior curve and the sacrum is rotated backward. The lumbar spine is flat and rigid. Usually there is a marked boarding of the muscles in the lumbar region and considerable hamstring spasm which may be unilateral. This group is representative of a fairly large number of cases in orthopedic practice.

Group 6.—The railway spine or litigation back. These patients usually endeavor to exaggerate the symptoms. In the absence of x ray evidence, or osteophytic outgrowths, tenderness, pain or stiffness in the region of the spine after an accident, which is unaccompanied by deterioration of health or confined to one spot, is usually psychic if complained of upon repeated examination.

TREATMENT.

In a consideration of the treatment of these injuries, it is well to classify the cases into those in which rest in bed is required, the ambulant case, requiring fixation either in the form of plaster of Paris jackets or other rigid apparatus, and those in which adhesive strapping or application of liniments, lotions and the like seem to be beneficial.

ACUTE INJURIES.

Posture.—In all moderately severe injuries to the lumbar spine or sacroiliac joints, the best results are obtained by putting the patient to bed for a variable period, until all signs of spinal irritation have subsided. The period of recumbency may be one, two or three weeks, depending upon the severity of the violence.

A proper position in bed in the treatment of these cases is of paramount importance. The treatment that is usually instituted is to put the patient to bed on his back with pillows under his head and shoulders. This, by flexing the back, puts the injured muscles or ligaments on a stretch, leaves them in the worst possible position for repair, increases the tendency to hemorrhage at the seat of injury, delays absorption of exudates and favors the formation of an excessive amount of fibrous tissue. When these patients finally leave their bed they frequently suffer from pain, stiffness and weakness due to causes mentioned above.

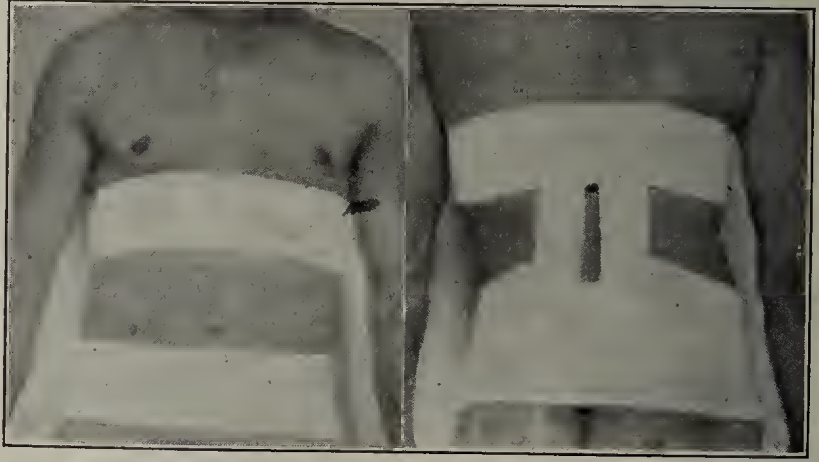

FIG. 2.—Splints applied. Anterior and posterior views.

The proper position is to put the patient supine either upon a Bradford frame or upon a firm nonsagging bed. A position difficult to enforce, but extremely desirable, is the prone position. In this posture the spine is the highest part of the body, and thus, passive congestion is prevented. Again, the absence of pressure is a great comfort when the back is unduly sensitive or tender. Furthermore, the spinal muscles attain their maximum relaxation when the body is prone. Finally this position allows for the ready application of local treatment to the injury such as light massage, baking, cupping and the like.

Plaster jackets.—After the patient is out of bed, the next problem is to know what to do with him. If the back still presents irritability, manifested by pain, stiffness and limitation of movement, it is advisable to apply some form of fixation. This may be in the form of a plaster of Paris jacket, a steel brace or a support usually employed by me made from wooden splints. If the plaster of Paris jacket is used, it should be removable; in other words, it should be cut down the middle. Massage, baking, and exercise are decidedly beneficial and should be employed at regular intervals during the period when fixation is being employed.

In the course of several weeks, the plaster of Paris jacket, or whatever form of fixation is used, can be dispensed with as the irritability of the spine subsides. Where osteoarthritic changes in the lumbar spine or sacroiliac joints are present, it is wiser to continue the use of spinal support for three or four months. These patients can go about their business quite comfortably. Under sufficient protection spasm subsides and motion returns to some degree. The joints are relieved of strain, adhesions, fibrositis, and secondary contractures lessen and sometimes disappear entirely.

Spondylitis is a progressive disease and at any stage fixation is the only efficient remedy.

Now we come to the patient whose injury is not severe enough to put him to bed and yet he requires some form of fixation to relieve strain at the site of injury. A light well fitting plaster of Paris jacket or a support made from wooden splints is used. These should be applied immediately after the injury is sustained and should be maintained for a week or two until all evidences of disability have disappeared. We can then employ physiotherapy. These patients, in the course of two or three weeks, are restored to normal function. The mistake is often made of treating these patients by means of adhesive plaster. It is obvious that adequate fixation cannot be obtained by strips of adhesive plaster applied to the back. In whatever fashion we apply it, its splinting effect is not sufficient.

Wooden splints.—I have used supports made of moulded wooden splints with considerable success in lieu of adhesive plaster, during the past year, in a number of injuries. These splints are applied to the lumbar spine and maintained in position by strips of adhesive plaster encircling the pelvis and lower thorax. They can be made by any surgeon from material at hand. The ordinary splint boards are cut into strips an inch and a half wide and from ten to twelve inches long (Fig. 1). For a muscular individual, four strips are used. They are immersed in water to soften them and are then moulded to conform to the shape of the lower back. After drying the shape is retained. Two strips are fastened together by means of adhesive plaster along their borders. These reinforced strips are then joined at the upper and lower ends, a space being left sufficiently wide to clear the spinous processes. Pads of felt, cotton, wool or any other soft material are then applied to the surfaces where pressure is to be exerted. Three strips of adhesive plaster three inches wide and of sufficient length to encircle the pelvis keep the splint in position. The upper end is kept in position by one or two strips two inches wide, which encircle the lower thoracic wall. To prevent irritation, the abdomen should be shaved. Cutting into the groin by the anterior strip is prevented by putting a layer of absorbent cotton or lint beneath the adhesive plaster along the lower margin (Figs. 2 and 3). Over this a muslin bandage is applied which finishes the dressing. The patients wear this support for a week. If the back is still irritable it is reapplied and worn for a longer period.

ADVANTAGES OF BACK SUPPORT.

In my experience this back support is a practical, ambulatory dressing. It is simple in construction, gives considerable comfort to the patient and provides adequate rest to the part without being cumbersome. It is particularly efficacious in sprains of the sacroiliac joints because the tight girdle of adhesive plaster offers a great degree of security to the part, the wooden uprights restraining the action of the erector spinæ muscle upon the pelvis.

Adhesive strapping. — Adhesive strapping is a popular method of treating many back injuries. Properly applied in the selected case it is of value, but used indiscriminately in all injuries it has been the cause of a great number of cripples. The indications for the use of adhesive strapping are the following: slight twists of the spine in which some of the spinal ligaments have been stretched, strains of muscular fibres, strains at tendonous insertions; in other words, any injury in which the symptomatology is of mild degree.

We should have a definite idea in mind as to what is expected to be accomplished by these strips of adhesive plaster. The prime object is to secure relaxation of the structures injured and fixation for a short period of time, and they are therefore applied along the muscle reaching from origin to insertion, and in this manner their splinting effect attains the maximum effect.

TECHNIC.

The manner of applying these strips of adhesive plaster is as follows: For example, in a strain of some of the fibres of the erector spinæ muscle three or four strips two inches wide and long enough to reach from the thoracic wall posteriorly to the crest of the ilium are applied on each side of the spinous processes. The tendonous expansion of this muscle upon the ilium and sacrum are fixed by several strips of adhesive two inches wide and long enough to encircle the pelvis. The application of adhesive plaster in this fashion restrains muscular activity, fixing the muscles which have their origin from the posterior surface of the ilium (the glutei).

USE OF GIRDLE.

In my experience the addition of the girdle of adhesive to the usual method of strapping makes it far more efficacious and of greater comfort to the patient. After four or five days the straps may have become loosened. They should be removed and the back thoroughly massaged. If there is still local pain and tenderness on motion, the straps should be reapplied and kept on for several days longer. Usually in these minor injuries, at the end of ten days or two weeks these patients have fully recovered.

CHRONIC BACK SPRAINS.

In the treatment of chronic back sprains or traumatic flat back, two methods are available.

FIRST METHOD.

First, rest in bed in a supine position upon a Bradford frame for from two to four weeks, with continuous traction applied to the extremities. By this means the irritability of the spine subsides, because strain and weight bearing have been removed. Muscular contractures are sometimes successfully overcome and joint surfaces separated. Through the application of physiotherapeutic measures, such as baking, cupping, massage, and manipulation, the restoration of function and relief of symptoms are established. It is wise, in these chronic cases, after the patient has risen from bed, to have him wear a spine brace or a plaster of Paris jacket for a month or two, so as to maintain the relaxation and fixation of the parts. The patient can get around very comfortably under such circumstances.

SECOND METHOD.

The second method of treating these traumatized backs is to rapidly and forcibly overcome the contractures and adhesions by manipulation under anesthesia. This treatment has been successfully employed by Wallace and Fiske with remarkably good results. The patient lies supine upon a strong table and first one extended leg, then the other, is forceably flexed upon the abdomen. By these manipulations the spine is flexed to the superlative degree. The ilium rotates backward upon the sacrum, the extended leg being used as a lever. Thus the normal lumbar curve is restored. A considerable amount of force is necessary and must be used, because we frequently encounter marked unilateral hamstring contractions.

This work is considered well done when we are able to flex the extended leg to an angle of about 90 degrees with the trunk. Wallace states that he has been able to flex the extended limb beyond this angle, and in some instances has been able to bring the foot almost up to the clavicle. In our experience these manipulations have not resulted so remarkably. Wallace also states that he has heard a distinct click which he attributes to the reduction of a chronically displaced sacrum. When we are satisfied that the posterior muscles and ligaments have been thoroughly stretched a plaster of Paris jacket should be applied, reaching from the lower scapula angle down to and including the pelvis. In cases of sacroiliac joint disturbances a long plaster of Paris spica, reaching from the waist line to the toes, should be applied. This plaster apparatus is worn for several weeks, after which a light spine brace, providing support to the lumbar spine and sacroiliac joints, should be worn for two or three months. The patient receives physiotherapy and back exercises several times a week. At the end of several months the back becomes quiet and the patient is symptomatically cured. As a matter of record an x ray examination should be made to determine the condition of the affected region.

TUBERCULOUS SPINE. TRAUMATIC SPONDYLITIS.

Tuberculosis of the lumbar spine or sacroiliac joints and traumatic spondylitis are treated either conservatively by means of apparatus or by operation. The conservative treatment of these cases consists in the prolonged use of a spine brace, until all evidence of the disease has disappeared. These patients, therefore, must be under observation for a number of years, during which time they must be given the benefit of the recognized régime for the tuberculous.

Fixation by means of the Albee bone graft seems to offer a quicker method of curing this disease, as in the case of the adult workingman. Even in the presence of sinuses, the disease has been arrested. aspiration is far safer than incision, even if it has to be repeated a number of times. Calot's modifying fluid is injected after the tuberculous material has been aspirated. A nontuberculous spondylitis of traumatic origin can be rapidly cured by the Albee method of bone grafting.

CHRONIC SPONDYLITIS.

The problem of a spondylitic back or chronic arthritis of the spine sustaining an injury requires careful consideration. These patients must not be treated lightly. We should institute adequate protection by means of apparatus, at the same time we should clear up all foci of infection that may be present.

CONCLUSIONS.

1. Minor injuries to the lower back are of frequent occurrence, many of them leading to prolonged disability. Inaccurate diagnosis and inadequate treatment account for the chronic disturbances of the back.

2. Injuries to the lumbar spine are grouped into the following classes: a, mild injuries such as contusions, strains of muscle fibres or ligaments; b, moderately severe sprains, fractures of vertebral processes without displacement and without cord involvement; c, injuries to the spine with cord and nerve injury; 4, injuries resulting in traumatic spondylitis or tuberculosis in patients normal prior to the injury; e, injuries to those suffering from preexisting chronic osteoarthritis, and f, hysterical spine or litigation back.

3. The most severe acute injuries to the back are treated by a variable period of rest in bed and by apparatus, namely, plaster of Paris jackets, wooden splints or steel braces.

4. Adhesive strapping should only be reserved for those cases manifesting a mild symptomatology.

5. Chronic sprains of the back are treated conservatively by preliminary traction of the spine upon a Bradford frame, followed by the use of a plaster of Paris jacket or brace and physiotherapy. The operative treatment consists of manipulation under anesthesia, to overcome adhesions and contractures and to restore the posteriorly dislocated sacrum to its anterior position, this to be followed by immobilization in apparatus and physiotherapy later.

6. Traumatic spondylitis and tuberculosis of the lumbar spine are treated either by apparatus for a long period of time or by operation (bone graft).

Suppurative Arthritis

By HARRY COHEN, M.D.,
New York.
Attending Surgeon, People's Hospital.

In this report only five cases of suppurative joints are cited. From a clinical point of view I appreciate that the number is far too small to be of real scientific value. However, when one considers that these cases are relatively infrequent and since the results in the newer method of treating these cases are almost uniformly good, I feel that the report of even so small a number will be of value in stimulating further interest in this subject. The good results in these cases are all due to the Willems method of treatment. In an article (1) that I wrote over a year ago, the method was fully described. In that article sixteen cases of all kinds of joint lesions were cited, but only one of a suppurative joint. Since then I have had five more and as remarked above the almost universally good results obtained warrant their reporting. To begin with the Willems treatment consists of early active mobilization of the involved joint after free incision. No drain is inserted into the joint. The usual results of this form of treatment are complete drainage of the joints, apyrexia throughout the entire treatment, limitation of the infection to the synovial membrane and the elimination of the postoperative atrophy. In suppurative joints I can see no contraindication to the use of the Willems treatment. When it is considered with what dread all surgeons used to approach these cases and the bad results that usually followed the treatment, the most common being either a high mortality, amputations or poor functional results especially ankylosis, it can be seen to what extent we are indebted to Willems.

CASE REPORTS.

Case I.—Suppurative arthritis of the right knee joint. H. H., aged seven, referred by Dr. M. Isenberg. This case was previously reported in the article published a year ago. However, it will bear repetition here. Admitted to the People's Hospital, July 26, 1920. Twenty-three days before admission he fell on a broken bottle, the glass penetrating the right knee joint. The knee gradually increased in size and symptoms of severe knee inflammation, including high temperature developed. On examination there were all the evidences of acute inflammation and fluid in the joint. In addition a healed wound was visible along the outer border of the patella. Röntgenograms showed the joint distended with fluid. An incision was made over the old cut and on entering the knee joint a large amount of thick yellowish pus was evacuated. The joint was washed out with Dakin's solution and immediate active mobilization was commenced. He was permitted to leave the bed on the fourth day, and encouraged to walk and climb stairs. The result was a complete cure in three weeks.

Case II.—Suppurative arthritis of left knee. R. B., aged twenty-one, referred by Dr. I. Jacobowitz, admitted to the People's Hospital December 3, 1921. History of three weeks' duration with pain, tenderness, swelling of the left knee; with septic temperature ranging around 104° F.; knee excruciatingly painful on any motion. Urethral and vaginal smears for gonococci were negative. The knee was aspirated and a large amount of thick greenish pus obtained. A bilateral incision, one on each side of the patella, was made and Willems treatment instituted. An immediate result was the dropping of the temperature to normal and a general improvement in her appearance. Before operation her condition was so severe that a fatal result was anticipated. She left the hospital in about four weeks with fifty per cent. mobility in the joint. The apparently poor result in this case, especially when compared to the others, we blamed partly on the patient as she was very much averse to carrying out the Willems treatment and only did so when severely urged.

Case III.—Suppurative arthritis of left wrist. S. S., aged ten months, referred by Dr. J. Abowitz and Dr. H. N. Appel, June 26, 1922. The patient had been sick one month, suffering at first with lobar pneumonia, then with measles, and then again with double pneumonia and finally with left cervical adenitis. At the suggestion of Dr. Appel I incised and drained the cervical abscess which healed in a few days. On July 1st the child developed a suppurative arthritis of the left wrist. Blood culture was negative. X ray showed the joint distended with fluid and on July 3rd I incised the wrist joint and evacuated a considerable amount of pus. Culture showed a staphylococcus. A rubber tissue drain was inserted to but not into the joint. Active and passive motion was instituted and a complete cure resulted in two weeks. The functional result was normal.

Case IV.—Suppurative arthritis of right ankle, complicating diabetes and erysipelas of leg. S. W., aged forty-five, referred by Dr. J. Weiss, May 15, 1922. The diabetes in this case had been under control for a long time. The sugar in the urine ranging from one half per cent to sugar free. Patient suffered several attacks of erysipelas, but this time suppuration developed in the right ankle joint. Incision under procaine with evacuation of the pus. Drainage to joint. Willems treatment with complete cure in two weeks.

Case V.—Suppurative arthritis of second joint of right ring finger. S. B., aged fifteen, referred by Dr. H. Goldstein, was admitted to the People's Hospital, August 21, 1922. Finger infected three weeks ago by the stick of a pin. Finger incised on four different occasions, by local physicians, but joint instead of improving swelled to more than twice the normal size. X ray showed joint distended with fluid and necrosis of articular surfaces with beginning osteomyelitis. The condition of the joint was so bad that amputation of finger was advised by a prominent surgeon because he believed that at best a stiff joint would result, and consequently the finger would always be in the way. However, free incision with evacuation of the pus and then Willems treatment resulted in a perfect cure in four weeks.

CASE VI.—Gonarthrosis of right wrist. S. B., aged twenty-eight, referred by Dr. A. Saiken, August 23, 1921. This case, although not a suppurative arthritis, represents an allied condition, and is therefore included in this report. There was a history of Neisser infection of three weeks' duration. The patient had been receiving active treatment with the result that the local infection had almost cleared up. About three days before I saw him there developed a typical gonarthrosis of the right wrist. The joint was markedly distended, red and excruciatingly tender as gonorrheal joints usually are. I applied a plaster of paris cast to the joint and kept it on for one week. After removing the cast the Willems treatment was applied and in another ten days he was entirely cured. It used to take me as long as two months to cure similar cases by other methods of treatment of which there were very many.

CONCLUSION.

In conclusion, in Willems treatment the results in suppurative joints have been more gratifying and that we can give to patients so suffering a fairly good prognosis.

One Hundred Cases of Weak Feet in the Adult With Pedographic Findings

By JACOB GROSSMAN, M.D.,
New York.

Chief of the Orthopedic Clinic, Stuyvesant Polyclinic; Chief of Orthopedic Clinic and Junior Adjutant Orthopedic Surgeon to Lebanon Hospital.

Although the recording of the impressions of feet in diagnosing abnormal conditions is not new, still the majority of orthopedists have not adopted this procedure. It is with the hope of having this method more universally used that this paper is written. Heretofore, a diagnosis was made upon the findings of an impression of the foot and a few objective signs and symptoms. No accurate record of the exact status of the foot at the initial visit was kept. The maintaining of such a record is important, for with it subsequent records or findings can be compared. In this way we have at our disposal an accurate method of determining the effects of our therapy. It also places at our disposal a permanent tangible record.

In recording the findings of a given case of weak feet, it is necessary to consider several points. First among these is the distance of the keystone of the bony longitudinal arch, i. e., the scaphoid, below a given line. This line is known as the Feiss line and is found by connecting the posterior border of the internal malleolus with the plantar surface of the first metatarsophalangeal joint. In the normal foot the scaphoid is usually one half inch below this line. As a rule in weak feet, it is usually more, varying from three quarters of an inch to one inch.

The second point to consider is the quality of the muscles of the plantar surface of the foot. Usually in weak feet the muscles are found to be poorly developed. In recording the condition of the muscles the terms good, fair, and poor should be used. This is important because a heavy, well developed group of muscles may give a flat impression, which flat impression may represent an apparent flat foot, the bony arch and the other findings being normal.

The third point to be sought for is the presence or absence of the juvenile fat pad. Here again the fat pad may give a flat impression in spite of the fact that the foot is otherwise normal.

The fourth point to be determined is the presence of eversion of the heel and heel cords. This should be recorded as slight, moderate, or well marked, as the case may be.

Finally the impression of the foot, or pedograph, should be taken. The pedograph varies and should be recorded as first degree weak foot, second degree weak foot, and third degree weak foot. The details of determining the degree of weak foot and the method of taking the pedograph follow. The patient is seated, the leg is extended and the bare foot is painted with an iron solution. The foot is then hastily placed on paper and the patient is told to place all the body weight on that foot. At this point the contour line is drawn by using a pencil held at right angles to the plane surface. This contour line demonstrates the amount of inversion of the ankle or eversion of the heels and heel cords. The foot is then removed from the paper, leaving a yellowish imprint. A solution of tannic acid is now applied to the iron imprint which turns a jet black, giving a record which can be preserved indefinitely.

The base lines and the auxiliary lines are now drawn on the pedograph for estimation of the degree of deformity. The first base line is drawn from a point posterior to the internal maleolus to the first metatarsophalangeal joint. The contour line extending beyond this line represents the degree of inversion of the ankle or eversion of the heels and heel cords. The line of axis weight bearing is next drawn, from the centre of the heel to a point midway between the first and second toes. A line is next drawn at right angles to the line of axis weight bearing from a point posterior to the heel. Another line is drawn also at right angles to the line of axis weight bearing, from the first metatarsophalangeal joint. Midway between the last two lines, also at right angles to the line of axis weight bearing, is drawn the line of estimation. The line of estimation is then checked. One check is placed at the outer border of the imprint, the other check being placed at the junction of the line of estimation and the first base line, or if valgus is present, at the junction of the line of estimation and the contour line. Midway between the two check marks on the line of estimation is the normal point, that is, the point where the inner border of the imprint meets the line of estimation in a normal foot. To the inner side of this point the line is divided into three parts representing the degrees of weak foot. The first check mark represents one degree, the second, second degree, and the third, third degree weak foot.

This procedure has been followed in one hundred cases of weak foot with the following findings.

The age of the youngest patient was fourteen years and the age of the oldest was seventy. There were thirty-two cases in males and sixty-eight in females. Most of the cases ranged between the ages of twenty and thirty. There were thirty-eight in this age limit. There were twenty-one cases between the ages of thirty-one and forty, fifteen between forty-one and fifty, twelve between fourteen and twenty, eleven between fifty-one and sixty, and three between sixty-one and seventy.

The occupations were as follows: Housewives, 59; clerks, 8; operators, 6; students, 5; salesmen, 4; cutters, 3; bookkeepers, 3; waiters, 2; policeman, 1; letter carrier 1; cook, 1; janitress, 1; barber, 1; tailor, 1; machinist, 1; peddler, 1; school teacher, 1; bartender, 1.

The majority of the cases occurred among housewives. The cause undoubtedly was the conventional shoes which the majority of these women wore, aggravated by the fact that they were obliged to do a greal deal of standing. Eversion of the heels and heel cords was present in all the cases. It varied from a slightly noticeable to a very well marked degree. In the normal foot the heels and heel cord are usually parallel to or converge slightly towards the midline of the body. In weak feet just the opposite is the case. The heels and heel cords diverge from this midpoint.

The juvenile fat pad was present in two cases. In these cases the feet made a flatter impression than they ordinarily would. This must be remembered when examining a case. The fat pad should always be sought for. In some instances the bony arch may be absolutely normal as demonstrated by other findings and still one obtains a second or third degree pedograph of weak foot. This is only an apparent weak foot pedograph and is the result of the fat pad.

The muscular development of the sole of the foot was poor in seven cases, good in three and fair in ninety. It is well to remember that a bulging, well developed muscular layer in the sole of the foot may also produce a weak foot pedograph, just as a fat pad would. One is not justified in making a diagnosis of weak foot in such an instance unless the remainder of the findings warrants it. Hence it is important, especially where the remainder of the findings is normal, to note whether the muscular layer is a bulging, well developed one.

The subjective symptoms in this series varied. In twenty-one they were unilateral and in seventy-nine they were bilateral. Forty-three of the patients complained of pain in the legs and calves, thirty-nine referred their pain to the feet, five complained of pain in the thighs, and four to the knees. One patient complained of a limp, five complained of turning their ankles easily, and four of them said that they tired very easily and could not walk as much as they desired.

The distance of the scaphoid below the Feiss line varied from three quarters of an inch to one inch. With some exceptions, the further the scaphoid was below the Feiss line, the more marked the weak foot appeared on the pedograph. In the cases in which the pedographs were normal and the other evidence leaned toward a diagnosis of weak feet, the scaphoid and the soft tissues were not depressed sufficiently to produce a change in the pedograph. These cases were usually early cases.

The pedograph was unilaterally normal in four cases and bilaterally in ten cases. It was abnormal unilaterally in four cases and bilaterally in eighty-six. Of the unilateral cases, one was a one degree weak foot and three were two degree flat feet. Of the bilateral, six were one degree weak feet, fifty-nine were second degree and twenty-one were third degree.

It is important to again emphasize that all these factors should be considered before attempting to make a diagnosis of weak feet. They should all be considered together and then only should conclusions be drawn from the findings.

CONCLUSIONS.

1. In arriving at a diagnosis of weak feet one should always take in consideration all diagnostic means at one's disposal. It is not sufficient to note whether there is eversion of the heels and heel cords or a flattening of the arch.

2. By means of the pedograph, the determination of the level of the scaphoid, the presence or absence of the juvenile fat pad, by consideration of the quality of the muscles of the soles of the feet and noting the degree of eversion of the heels and heel cords, one can record fairly accurately the status of a foot condition.

3. While this method is not infallible, yet in it we undoubtedly have the foundation upon which we can accurately study successive changes in the foot.

4. Poorly fitting, conventional shoes produce the majority of acquired foot deformities.

5. Preventive measures will in a large number of instances obviate permanent crippling and suffering. Good orthopedic shoes will usually accomplish this.

6. In my experience it was noted that a great number of weak feet met with in the adult could be traced back to childhood. In a paper (1) recently published I noted the findings of the value of pedographs in recording and diagnosing abnormal foot conditions in children. Were the method as outlined in this paper to be followed, it is a certainty that the majority of weak feet found in adult life would be less often encountered.

Editorial Articles

THOR.

A heroic figure, known among certain groups, is Boris Sidis. It is true that he is not thoroughly appreciated for his innate modesty and ultraconservatism have kept him hidden from the gaze of the vulgar public.

He may be pictured as the popular concept of the God of the Old Testament—fearless, virile, just. It can be foreseen how certain critics, in their spleen, will be prompted to call him cruel and vindictive. Others may go so far as to call him cowardly, but this should not be tolerated for these accusations may be refuted by quotations from his own *Nervous Ills,* which is a book published by Badger in Boston. To anticipate his critics, we will take up the defense of this great man. To prove his fearlessness, we examine his attitude on psychoanalysis. Of course it requires courage to combat a thing like psychoanalysis. A list of the leading neuropsychiatrists who subscribe to this pernicious doctrine includes such men as Bianchi of Italy, Varendonck fo Belgium, Jelgersma, Kappers of Holland, Bleuler of Zurich, Delgado-Valdizau of Peru, Stoddart and Jones of England, White, Jelliffe, Kempf, and a host of others in this and other countries throughout the world. What evil *dæmon* could have taken possession of these otherwise reputable men? There should be a senatorial investigation! But let us not get into a passion over the matter but listen attentively to the words of our Jahovian oracle. "Many take up psychoanalysis as a sort of mental masturbation which in the long run is sure to play havoc with their nerves and mind. Freudian psychoanalysis should be openly declared a fraud. Psychoanalysis is a sort of mormonism. Psychoanalysis is a sex religion. The psychoanalyst with his allegories, symbolism, sublimation, incest, phantasies, bisexuality, sexual suppression, mother complexes, œdipus and electra phantasms, and all the other complex psychoanalytical instrumentalities is an excellent example of sex obsessed, delusional dementia præcox."

Not only does he come right out and give a minute critique of psychoanalytical theories but he presents a diagnosis of the psychotic ailment of the psychoanalysts. This should answer the question of his courage. Others may contend that psychoanalysts suffer from paranoia, cyclothymia, or other psychoses, but we are inclined to agree with Sidis—dementia præcox. Perhaps another time he will go more fully into the description and tell us, who are breathlessly awaiting the word, what particular form of precox the analysts suffer from, catatonia, hebephrenia; most likely it is a complex paranoid form with very early moral and physical deterioration.

Sidis ascribes all nervous ills to *"selfpreservation and the fear instinct."* He sums up in various places, *"Functional psychosis or neurosis is an obsession, conscious and subconscious, of the fear instinct." "Neurosis is a disease of selfpreservation and fear." " . . . selfpreservation and fear are at the bottom of the psychopathic neurotic constitution."* No doubt the reader understands all this and finds himself in accord, but we must first answer those bothersome critics. First among them will be those who insist on finding a cause for the fear. Among them will be those who say one cannot fear unless there is doubt. Where fear is there hatred is also. Fear cannot be present without impotence. It is necessary to find out the origin of these more primary causative factors before we can deal intelligently with the fear manifestations. Why bother to answer these quibblers who are continually taking the joy out of life with their everlastiing searching for what they call truth. Is it not enough that an eminent man like Sidis says "fear?" Enough.

Then they will say: "How can one have an obsession of an instinct?" We will not even deign to answer. Sidis has probably selected his words unfortunately. He no doubt was thinking of weightier matters when he wrote this. They will then no doubt want to know what gibberish is meant by "*a disease of selfpreservation.*" Why can't a man have any disease he chooses? There are diseases of the appendix or mind—why not of selfpreservation, esthetics, or calisthenics? One must have a soul to appreciate Sidis's epigrammatic utterances, and who ever heard of a psychoanalyst with a soul.

Let us now briefly consider Sidis in some of his noble constructive phases. His attitude towards his patients may be inferred from the following rather touching description:

". . . 'tigress,' 'satan,' 'fiend,' would be more appropriate appellations. She was a firebrand from hell, a firebrand fanned by the furies of self and fear." In another instance she is described as "a regular vampire, sucking the life blood of her family. The woman was obese as a hippopotamus, well nourished, with a florid complexion, and with an appetite that would shame a Gargantua." We can hear the critis harping, "Sidis shows his affective state in his ridicule and hatelike descriptions of his patients. A scientist who was not emotionally swayed would not use terms such as these in talking of unfortunate neurotics who came to him for understanding and aid. A physician cannot understand his patients or psychological processes when he allows his affective state to stand between him and his patients. They may even have the temerity to add that this exhibition of hate implies impotence and revenge. But we will not heed these trouble makers. Surely Sidis can call his patients anything he pleases. It just shows his bravery and he probably did not apply these terms, that may be considered a bit harsh to them, to their faces. At any rate one may be sure that he does not discuss sexual things with them for right in his introduction he definitely shows his attitude toward this nastyminded procedure.

There may be those among the critics of the great Sidis who say his book is more of an autobiography revealing his hatred, impotence and the great phobia he has of psychoanalysis. They may even be foolish enough to say he has harped on his pet "fear" theory to the point of making himself ridiculous and causing the whole book to have a distinct paranoid trend. We shall not even discuss the matter with those who are lowminded enough to suggest such evil thoughts.

What better answer can we give to all the critics of Sidis than his own words: "I kept on treating her by the hypnoidal state." This should silence them all.

THE PROGRESS OF MEDICAL JOURNALISM DURING THE PAST ONE HUNDRED YEARS.

The progress of medical science in all its branches during the past one hundred years has exceeded that of any previous period of the same length. This is to say that more important discoveries have been made, side by side with greater advances in clinical medicine and surgery. Pasteur whose centenary has just been celebrated, revolutionized the practice of medicine by the results of his investigations into germ life, and helped to render it a more or less exact science. Without the aid of medical journalism progress might have been much slower. Intelligent, shrewd and sane journalism is a potent force for spreading knowledge and for forming opinion.

The *Lancet,* which at the close of this year will have been in existence for one hundred years, has been a pioneer in this direction. It may thus be classed as fittingly representing medical journalism. Established in 1823 by Thomas Wakley, one of the most fearless of reformers, it has played a part in the introduction of most of the reforms which have taken place in the British medical profession and in all things appertaining to medicine and health in Great Britain since its foundation. Its journalistic activities have not been confined to the country of its birth, but by publishing news of medical interest it has fulfilled the original and ambitious intention of its founders to notice medical affairs in England "or in any part of the civilized continent."

The *Lancet* supplies an excellent illustration in point of the strides made by medical journalism. In the first number issued on October 1, 1823, clinical notes from three widely separated towns were published, an earnest of the avowed intention of giving news from far off places. Its centenary year opens in the number of January, '23, in which are published communications from London, the British medical centers, Edinburgh, Vienna, Tokyo, Paris, New York, Philadelphia, Cape Town, Stockholm, Zurich, Madras, Bukharest and Berlin. The *Lancet,* then has symbolized adequately throughout its existence mainly on account of its age, but also because of its able editorial conduct, the advance of medical journalism during the past 100 years. While moving with the time it is more conservative than American medical journals. However, this is in keeping with the manners, customs and tastes of their respective readers. A study of the *Lancet* from its earliest days provides an engrossing retrospect of the ups and downs of medical science and its practitioners during the period covered, and the progress of medicine towards the light. At the same time, it exhibits the advance of medical journalism or rather is a mirror of its advance in all civilized countries.

THE COMPLICATIONS OF FRACTURES OF THE ASTRAGALUS.

Fractures of the astragalus are serious only from the viewpoint of function; in most cases the fracture is a closed one and does not require any surgical intervention for saving either the limb or the patient's life. Nevertheless, in some cases, quite rare for that matter, the fracture has been a compound one and deaths have been reported, for example in Barral's case in which a transverse buttonhole wound of the instep, with quite clean cut borders, allowed the escape of the head of the astragalus; death from infection occurred one week later. Other cases, especially those of Thierry and Blum, concern compound fractures, but the patients recovered.

Briefly stated, in some very exceptional cases the fracture may be compound and in the past the prognosis was most serious because it meant amputation —and death. At present infection can be controlled and prevented by early and thorough cleansing, or by primary astragalectomy undertaken at once.

The solutions of continuity of the integuments produced the exaggerated projection of either the external malleolus or the astragalus. At other times the fragment of astragalus dislocated either forward or backward, menaces the skin, gangrene sets in and transforms a fracture primarily closed into a compound one which has the same prognosis and the same treatment.

However, in two reported cases, death took place in simple fracture of the astragalus. In the first, reported by Pinnaté, the patient fell from the second story of a building and died twenty-four hours later, after presenting signs of pronounced syncope. At autopsy the capillaries and arterioles of the lungs were found distended and gorged with fat globules to such an extent that in the lungs it was impossible to find any spot not filled with fat. Therefore, a fat embolus was evidently the cause of death. In another case reported by Ménissez, death occurred from septicemia one week after the accident. There was a comminuted fracture of the astragalus without any lesion of the integuments. The bone was reduced into many fragments.

Briefly speaking, with the exception of some rare cases of early and rapid death, and in which the violence of the shock was far more important than the fracture of the astragalus itself, these fractures, like all other joint fractures, are serious only when they are compound. And even in these circumstances, the gravity, which is due to infection, can be eliminated or controlled by doing an astragalectomy without awaiting the onset of septic symptoms.

The prognosis *quoad vitam* of these fractures is consequently not serious in the majority of cases. The same cannot, however, be said of the function prognosis, and these fractures, often unrecognized or badly treated, as happens occasionally, result in tardy complications, the first of which is ankylosis. According to the lapse of time since the fracture this ankylosis will be both osseous and fibrous. The changes in the shape of the fractured bone and the displacement of the fragments on the one hand, and on the other the changes in the joint cartilages, fibrous bands and osteophytic productions, are the lesions creating ankyloses in bad positions.

But deformities of the bone or certain of its undisplaced parts also play a part in the production of ankylosis. In a case reported by Delore there was a fracture of the neck with flattening of the pully and this crushing had resulted in widening of the astragalus transversally. The pully broadened in the same direction therefore hit against the malleoli between which it remained with difficulty. There was also an elongation in the anteroposterior direction, especially behind, which explained the sensation of bony resistance which could be perceived behind the tibia.

In some instances the bone deformity constitutes the principal obstacle to movement. In one case (Albertin) the astragalus was packed together in such a way that the neck disappeared from fusion of the head with the body of the bone. Many similar cases could be quoted. Displacement of one of the two fragments, more or less deformed and adherent will also create functional disturbances. In Herbert's case the displaced posterior fragment, dislocated backwards and outwards, was adherent to the surrounding structures and had to be removed by morcellation.

The treatment of comminuted fractures of the astragalus requires total astragalectomy at once and this operation is the method of choice in cases of old fracture. The results of this operation may be said to be excellent so that, at present, with the aid of radiography and the judicious selection of the treatments at our command the prognosis can be generally regarded as good.

AUGUSTAN AGE OF SCIENCE.

The past one hundred years may, perhaps not inaptly, be termed the Augustan age of science, including, of course, medical science. It is extraordinary to think that a century ago nothing was known of microorganisms and their relation to disease. The science of bacteriology is comparatively new. Pasteur, the French chemist, was the father of bacteriology and taught that the long held belief that living organisms arose spontaneously was wrong, and that such organisms were never created but grew from others. Moreover, he showed that particular forms of germs were the causes of putrefaction. This discovery gave Lister the idea of antisepsis which he applied in 1866. By this method of treating wounds it was practically demonstrated that, when the microscopic living causes of decomposition were kept away from wounds, such hospital fevers as pyemia and gangrene, which had previously exacted a fearful toll in life and suffering, vanished at the same time. Pasteur, undoubtedly the greatest man of his time, and one of the greatest of all time, discovered the minute organism associated with puerperal fever and it was upon the firm foundation of the researches of this modest French investigator that Lister based his methods for preventing septic disasters. Of course this mode of treatment, in conjunction with the discovery of anesthetics in 1844, revolutionized surgery, robbed it of its chief terrors, and opened up an immensely increased range of surgical operations.

Parasitology is of even more recent growth than bacteriology and is yet in its adolescence. Its discovery is as momentous, perhaps even more so, than that of bacteriology. Laveran, another brilliant Frenchman, in 1880, suggested that malarial fever was caused by minute animal parasites, and he and Koch pointed out the possibility of mosquitoes being the hosts of the germs. Sir Patrick Manson carried the suggestion considerably further, but it was left for the Scotchman, Roland Ross, in India, to confirm the matter by an extended series of experiments. The American, Walter Reed, and others working in the same direction, found that yellow fever was carried and transmitted to man by a certain species of mosquito, and, acting upon these discoveries, the Panama Canal was made possible by the destruction of the breeding places of the mosquitoes. Many pest holes of tropical climates, in former times almost uninhabitable by white men, at least for any length of time, on account of malaria and yellow fever, have become comparatively healthful places of residence for the Caucasian race.

Again, plague is an insect borne disease. This fact was proved in 1894 by the Japanese scientists, Yersin and Kitasato, who showed that it was caused by an exceedingly minute vegetable parasite conveyed by fleas from rats to men.

Sleeping sickness was shown to be conveyed by the tsetse fly. American investigators showed that typhus fever was carried and transmitted to man by lice, and that various other diseases, were similarly transmitted by other insects. As said before, parasitology is a new science, but knowledge of it is progressing rapidly. It is only when the causative organisms have been discovered and the carrying agents are known that really efficient preventive measures can be employed.

Another recent medical discovery is that the internal secretions play an important part in the harmonious working of the human machine. A good deal is known of the thyroid gland, less of the pituitary body, and less still of the suprarenal, while knowledge of the other glands is yet somewhat vague though continually increasing. It is believed by some that endocrinology will be the medical science of the future and that when a really accurate knowledge of the ductless glands has been gained, a long step forward will have been taken. However, organotherapy has already achieved a considerable degree of success which, as further advances are made in that branch of medical science, will undoubtedly increase. In the human body disorders of a single organism will disturb the working of the entire mechanism.

The vitamine question is one that has bulked large of late. These extremely minute and somewhat elusive substances are as essential to nutrition and good health as perhaps are the proteins, fats, carbohydrates and mineral salts. However, it is difficult to adjudge the exact position each of these substances holds in maintaining the nutrition and, consequently, the health of the body. Beriberi is a deficiency disease caused by the consumption of polished rice, vitamines necessary to nutrition having been removed in the process of milling and polishing. There are other socalled deficiency diseases, although rickets, once thought to belong in this category, is now the subject of much argument. Some think that the vitamine theory has been somewhat overdone and, while the presence of vitamines is important, believe that the factor of greatest moment is a well balanced diet. The mineral salts are of the first importance and if they are lacking or deficient, especially the calcium salts, disagreeable or even serious results will follow. Mineral salts are present in the husks of grain, but by modern process of milling, both vitamines and mineral salts are removed. Metabolism is kept up to its proper standard by a diet which contains in due proportions all the food elements which go to make up a well balanced diet, one which is adapted to the climate, to conditions of work, and to the individual.

However, the discovery of the internal secretions and their importance in the human economy is valuable as, in a lesser degree, is the discovery of the vitamines and their use. Synthetic chemistry has done a good deal for medicine and it may be said with emphasis that the progress of medical chemistry during the foregoing century has been remarkable. It has been predicted by some who have the right to speak with authority that in chemistry the human race may find salvation, that is, from the point of view of health. The past one hundred years has been the Augustan age of science in which medical science has played its part.

WASHINGTON AND LINCOLN.

That good physique and health do not necessarily go together is abundantly illustrated by the lives of our two greatest Americans.

Both Washington and Lincoln were of large build. The former, according to the letter which he wrote when ordering a suit of clothes from his London tailor, was "six feet high and proportionately made—if anything rather slender than thick for a person of that height." The "best weight of his best days" was 220 pounds. Lincoln was four inches taller and weighed about 180 pounds, was of narrower chest and less erect. Both lived, in youth, much the same out of door life—Lincoln having the ruder existence. Both were very muscular, being the champions of sport in their respective days and localities. Both were robust in mental qualities as in physical strength and endurance. Yet when it came to resistance to bacterial infection, the contrast was as remarkable as was the comparison in other respects.

Washington, at sixteen, had malaria "to an extremity." While in the Barbadoes with his brother who was suffering from consumption, he contracted smallpox, which scarred him for the rest of his days. Soon after returning from the Barbadoes he was taken with "violent pleurisy" which reduced him "very low" and which is said to have caused the deformity of his chest. Again, in the Braddock campaign, he suffered from malaria, and in 1757 was obliged to leave his command and return home on account of dysentery. He had fever for four months, and, believing that he had become a victim of consumption, looked forward to "approaching decay." Three years later he was again ill with malaria. He had several attacks of "influenza," and in one of these, during his presidency, his life was despaired of. For nearly six weeks he was unable to transact business. Again after leaving office he suffered from malaria. His latest illness was quinsy contracted from exposure to cold and wet. Washington suffered also from inflamed gums and carious teeth, and by the age of sixty-three he had lost all these troublesome organs.

In contrast, Lincoln is said never to have been sick, although he would have been considered, at a glance, of inferior physique.

It may be of interest in this time of threatened return of smallpox that, when this disease attacked the Continental Army, Washington endeavored to have the Assembly of Virginia repeal its law against inoculation for this disease. He also urged his wife to secure protection against the disease by this means.

Both Washington and Lincoln were temperate in all things. Both, but especially Washington, led the out of door life, but neither fine physique nor temperance can take the place of bactericidal properties, inherent or acquired, in the tissues, when it comes to dealing with invading microbic armies.

VITAMINES.

A great deal of activity has been aroused by the publicity which has been given the subject of vitamines. As in every similar situation, many loose statements and assertions have been made. Various vitamine products have been put on the market both for the public and for physicians. Those which are designed to meet the requirements of the neurotic who purchases any new popular product in order to gain an open sesame to that golden state known as perfect health we shall not consider. For these blind purchasers are as willing to be duped by one preparation as another and it little matters whether they are given cobwebs or eel's feet.

The physician—that is, most physicians—want a reliable product that they may learn of its activities and so be able to judge what results are being effected. There are conditions in which it would seem reasonable to suppose that a dependable vitamine product would be a valuable aid. Just how valuable we may not be able to assert at present. At any rate, we must know the potency and reliability of the product we are using.

To this end a series of experiments were conducted by the Connecticut Agricultural Experiment Station at New Haven, Conn. They experimented with a number of vitamine products which are on the market and published the results of their findings in their Twenty-seventh Report on Food Products and Fifteenth Report on Drug Products (Bulletin 240, August, 1922). This piece of research work was most carefully done and the bulletin may be procured on request without cost.

It would seem advisable for all physicians interested in the vitamine question to examine this short report so as to understand better the potency of the products which they may use.

◆

Obituary.

DR. JOHN H. LARKIN, M. D.,

of New York.

Dr. John H. Larkin, assistant professor of pathology at Columbia University School of Medicine, died on Wednesday, January 17th, of pneumonia. Dr. Larkin was born in New York fifty-three years ago. He joined the staff of the College of Physicians and Surgeons immediately after his graduation from that institution in 1894. He had already been graduated from Manhattan College in 1891. He contributed many articles on his speciality and related subjects to medical journals and scientific publications, and had collected many valuable specimens for laboratory and research work. In the position of chief coroner's physician of New York city, which he held for several years, he took a prominent part in several notable criminal cases. Since 1911 he had been director of the pathological laboratory of the City Hospital. He was also professor of pathology at the Flower Medical School and consulting pathologist to six New York hospitals. He was a member of many medical societies, including the New York Academy of Medicine and the New York Pathological Society. He is survived by his son, John H. Larkin, Jr., who is studying medicine at Columbia. Dr. Larkin was one of the leaders in his special branch of medicine and his death is a real loss to the profession.

HERBERT EDWIN BARIGHT, M. D.,

of Saratoga Springs, N. Y.

Dr. Herbert Edwin Baright was born on January 3, 1868, at Poughkeepsie, N. Y. He was graduated from Cornell University, obtaining the degree of B. S., in 1889, and obtained his degree of M. D. at Ann Arbor Medical College in 1893. After that he was physician to the Hudson River State Hospital for four years and then to the Clifton Springs Sanatorium for seven years. He studied medicine in Vienna in 1911 and studied and traveled in Europe in 1906 and 1907. While in New York he was associated with Dr. Ludwig Kast from 1911 to 1915 and was instructor in the Post-Graduate Hospital Medical College. He was a member of the American Medical Association and a fellow of the New York Academy of Medicine. In 1915 he established the Saratoga Springs Sanatorium, where he practised until his health failed. He married Irene Benham in 1907. His mother, Dr. Julia Baright, is a physician living in Florida.

Dr. Baright's kindliness of disposition and gracious personality were of great assistance in his skilful handling of patients. His sanatorium was well known for its excellent management and for the individual care given to patients. This could only have been accomplished by the infinite pains and personal care of the doctor and his wife who survives him. The close attention to his patients and unswerving interest in diagnosis and treatment gave Dr. Baright little time for recreation, a fact which undoubtedly shortened his life. His interest in medicine was exceeded only by his own natural modesty.

HERBERT EDWIN BARIGHT, M. D.

The example of his great and unselfish service to humanity represented the ideals of a great physician and will be of lasting value to the medical profession.

News Items.

American Laryngological Association.—The American Laryngological Association will meet at the Hotel Ambassador, Atlantic City, May 16, 17, and 18, 1923, under the presidency of Dr. Emil Mayer, of New York City. Dr. George M. Coates, of Philadelphia, is secretary.

New $500,000 Hospital for Jamaica.—The cornerstone of the new $500,000 hospital for Jamaica was laid on Van Wyck Avenue, Brooklyn, on December 7th. William C. Reid, president of the Jamaica Hospital, delivered a short address in which he praised the untiring efforts of those who made the new hospital possible. Mr. Reid placed the stone, assisted by Miss Mary R. Gale.

Annual Meeting.—At the recent Council meeting it was decided to hold the annual meeting of the American Gynecological Society in Hot Springs, Va., May 21, 22, and 23, 1923.

Physiotherapy Course.—A course in physiotherapy for the training of aides offers to women a thorough training in the science and practice of physiotherapy. The work will be given at the Walter Reed General Hospital, Washington, D. C., beginning February 27, 1923, and will cover a period of four months.

Eyesight Conservation.—The Eyesight Conservation Council of America has issued Bulletin No. 2 which presents a program for Eyesight Conservation Day in the public schools. The Bulletin outlines a procedure suitable for large and small schools for the examination of the eyes of all school children. The Council furnishes a vision chart for schools and in addition to the program for Eyesight Conservation Days in Schools has published folders in story form emphasizing the care of the eyes. Data may be secured from the Council whose headquarters are at the Times Building, New York City.

Dr. Michel Sails.—Dr. Leo L. Michel, genitourinary surgeon to the Hospital for Joint Diseases, New York City, has sailed for an extensive tour of the hospitals and institutions of England, France, Germany, Austria, and Italy. He will review the recent work of his specialty, as well as the new researches of Voronoff and Steinach. The new building of the Hospital for Joint Diseases (in the course of construction) will benefit from this trip as Dr. Michel will be on the alert to convey impressions for improvement in apparatus and technic.

Japanese Medical Commission to Visit the United States.—A recent cable dispatch from Tokyo announces the appointment of Baron Yoshihiro Takagi, chief surgeon and professor of surgery in the Tokyo Charity Hospital and Medical College, as a member of a commission of six Japanese doctors who will arrive in the United States early in March as guests of the Rockefeller Foundation for the purpose of studying American and Canadian medical institutions and methods.

The commission was appointed by the Japanese Minister of Education, Dr. Eikichi Kamada, to whom the Foundation's invitation was extended by President Vincent through Baron Shidehara, the Japanese Ambassador at Washington. Nominations for membership in the commission were made by the Japanese Committee for Graduate Medical Education in the United States, headed by Baron Sakatani, under whose auspices a number of Japanese physicians have pursued postgraduate studies in the United States.

THE FIFTH AVENUE HOSPITAL.

The Fifth Avenue Hospital is the result of the consolidation of the old Hahnemann Hospital and the Laura Franklin Free Hospital for Children. For several years before the war the trustees and medical staff of the Hahnemann Hospital had been considering replacing the old building, which had served the public for more than fifty years, with a new structure, so planned that the "ideal type of hospital service might be available to all persons, irrespective of class, creed or color." Investigation showed that the really poor are provided for in the city hospitals, and in privately endowed institutions. Persons of unlimited means may avail themselves of all the advantages and luxuries to be purchased in modern hospitals. But a large middle class exists, consisting of people of limited means who do not wish nor need to be charity patients, yet who are not able to afford the privacy and care that they would like to have. "To provide this in between class with all of the necessary comforts and the privacy of a single room is the great ideal around which this hospital has been constructed," says the present director, Dr. Wiley E. Woodbury, "but, in order that all classes may be accommodated, ample provisions have been made to care for persons of unlimited means as well as for those who are extremely poor. The rates authorized by the board of trustees are from nothing up."

A most imposing and impressive structure the Fifth Avenue Hospital is, occupying a whole block front on Fifth Avenue between 105th and 106th Streets just across from the Central Park Horticultural Gardens. The architecture might be described as an adaptation, to a modern skyscraper type of building, of North Italian Renaissance lines and a Spanish Mission roof. The building is nine stories high, with a central dome containing three more stories, and with a basement and subbasement. It is constructed in the form of an x, since this plan provides each of its three hundred rooms with outside lighting and exposure. This character of the rooms, and the fact that each patient has a private room, except on the children's floor, are the special and outstanding features of the hospital. Another feature is the doing away, as far as is compatible with medical standards, of everything suggestive of a hospital atmosphere. This has been done with notable success in the patients' rooms, which are exceedingly attractive with their pretty wooden furniture, painted in the most modern style, comfortable chairs, harmonious rugs, and, in some instances, a beautiful outlook over the park. Each room has a connecting lavatory, some have bathrooms, and others are in the form of suites. The walls are a soft French gray, and even the beds are enamelled to harmonize with the walls and furniture. On practically every floor there are waiting rooms for visitors, and these, too, are comfortable and attractive. Even the anesthetizing rooms of the operating department on the eighth floor masque their purpose in their decoration and furnishing, which resemble that of small parlors. The corridor walls are buff and tan, and further variety is added to the color scheme by having some of the rooms, among them the patients' solarium on the tenth floor, done in a soft grayish green. The nurses' rest room on the ninth floor is a large, sunny apartment overlooking Fifth Avenue and Central Park. Every floor has a loggia overlooking the park where patients or staff may sit or walk in the open air, in case they are not able, or do not wish to take advantage of the four promenade roofs on the tenth floor. Here on the roof the patient may remain all day yet receive as usual his regular meals and treatment.

FIFTH AVENUE HOSPITAL.

The first floor of the hospital contains the offices of administration, dining rooms for the resident staff and nurses, living quarters for interns, and private suites for physicians who wish to take advantage of the facilities of the hospital. These consist of a reception room, an office, and an examining room, and are so situated that patients may be admitted by a private entrance. The social service department has its headquarters on this floor. The chief function of this department is the investigation of nonpaying cases before they are admitted to hospital.

The second floor, called the Laura Franklin-Delano Foundation, is devoted exclusively to the care and treatment of children. On this floor, instead of single rooms, are large, many windowed apartments, some of which have been divided by glass partitions into isolation cubicles. Here also are playrooms, both indoor and out, a school room, a dental office, and other facilities. Outpatient clinics are held here daily from two to three.

The third, fourth and fifth floors, consisting chiefly of patient's private rooms, show the x plan which is one of the features of the Fifth Avenue Hospital. The four corridors, on which these rooms open, radiate from a court in the central rotunda. Around this court are the entrances to the elevators, and opposite them are the open supervisor's office, commanding a view of the elevators, the visitors' waiting room, and the whole length of the four corridors; adjoining the supervisor's office a small service room for the preparing of special treatments; back of this a rest room for special nurses; and behind the elevators two completely equipped treatment rooms. The fourth floor contains rooms for the supervisor's and the pupil nurses, and the third those for employees.

The sixth floor is devoted to maternity cases, with provisions for maternity clinics on Tuesdays and Thursdays. Here prospective mothers may be received and given two weeks' board, care and treatment, including delivery and treatment of the baby, all for the sum of $75. This floor accommodates thirty-eight adults and forty-five babies. There are three delivery rooms, one of which is especially equipped for the care of infected cases. The rooms on this floor have been provided with sound proof walls and ceilings, so that all noise has been reduced to a negligible quantity.

The seventh floor is much the same as the third, fourth and fifth, except that the rooms here are somewhat larger, several of them have private baths, and a number are arranged in suites to be thrown together when necessary.

The eighth floor is devoted wholly to the various scientific departments. The operating rooms are seven in number and occupy the northeast wing. These include a clinic operating room, two private operating rooms, an operating room specially equipped for genitourinary cases, with a cystoscopic room nearby, a plaster room for the orthopedic service, and special operating rooms for the eye, ear, nose and throat departments. There are also surgeons' scrub-up rooms, supplied with all the latest scientific apparatus to insure sanitation and asepsis, sterilizing units for the operating rooms, and a special instrument and supply room with the necessary articles continuously available for every type of operation. Each operating room is equipped with a recessed cabinet in the wall for dressings and supplies.

In the operating rooms the color scheme of gray is carried out in the dark gray tiling and very pale gray upper walls and ceilings, giving practically the same light effects as white. The furniture is also light gray. Regular operating hours are daily from eight a. m. until four p. m., but emergency cases are received at all hours. On this floor a reference library for the staff will occupy the space used on the other floors for the visitors' waiting room, and there is also a staff room for medical instruction and demonstration.

The southwest wing of the eighth floor contains the pathological and bacteriological laboratories. This department is equipped with a dumbwaiter service for the transportation of specimens direct from the other floors. In the southeast wing are the gastroenterology and x ray departments, with full equipment; and in the northwest wing are rooms for special treatment and examination, with a basal metabolism apparatus, an electrocardiograph and other equipment. On this floor also, as has been said, are the anesthetizing rooms.

The ninth floor is given over to the use of the nurses; the tenth has the open air roofs, the patients' solarium, and the quarters for the animals used in experimental research in the hospital; on the eleventh is installed the automatic dial telephone, and on the twelfth the great plant of the ventilating system.

There are also a basement and subbasement. In the latter are located the morgue, the autopsy rooms, the disinfecting and the incinerating plants, the fan rooms and the boiler plant. The main basement contains one of the special features of the Fifth Avenue Hospital, namely, the central service department. This is situated in the centre of the basement, adjacent to the linen room, surgical supply department, pharmacy, store rooms, general kitchen and diet kitchen. Four electric dumbwaiters and a freight elevator transport necessary articles from this department to the various floors of the building.

Orders for these necessaries are transmitted to the basement direct from the various floors by means of a telautograph in the supervisor's offices and automatic telephones. The general kitchen and the diet kitchen prepare the food, which is placed on trays that are immediately transferred to large, electrically heated, dumbwaiters, and so carried up to the various floors. When the meal is finished, the trays are returned to the basement. The other chief department of the main basement is that of the surgical supplies. This division has the complete handling of the sterilizing of the hospital.

As the Fifth Avenue Hospital has been receiving patients since last July only, it is perhaps too early to comment on the practical working out of its departures from ordinary hospital construction, equipment and administration. Inquiries as to whether a lack of skylights and the gray wall coloring in the operating rooms might not obscure the lighting to some extent, were answered by the statement that the large, complex and specially constructed electric lights directly over the tables obviate this possible criticism. Whether or not patients may be cared for as successfully in private rooms without special nurses as in wards remains to be proved by the Fifth Avenue Hospital system. According to this system the patient, when he wishes attention of any kind, presses a button in his room, which turns on a green light in the corridor above his door, and another in the supervisor's office. These lights stay on until the nurse goes to the patient's room and puts them out by pressing another button. If the patient is considered too sick to be left alone for part of the time, he is required to have a special nurse. All delirious patients, patients recovering from the effects of anesthetics, and, of course, critical cases of all kinds are also required to have special nurses.

There are various other minor points, the working out of which will be watched by New York nurses and physicians. Members of the staff report that to date the system as a whole has worked most satisfactorily, with minor modifications, as methods are being tried out. The administration is most cordial in its welcome of those interested in its plans and problems, thus enhancing, in contrast to an institutional or hospital atmosphere, the more cheerful and informal feeling given by pleasant, homelike surroundings, which have been proved not only possible but practicable, even in an institution so huge and so highly systematized as the Fifth Avenue Hospital.

VIENNA LETTER.

(From our own correspondent.)

Vienna, *December* 10, 1922.

AROUND THE SICKBED OF THE GERMAN PEOPLE.

The German medical world is making preparation for great demonstrations with which they intend to direct the attention of the world to the bodily degeneration of the German people in consequence of their economic misery. The medical faculties of all the universities, medical organizations, and the representatives of Germany are sending out a proclamation to the world pointing to the unbearable conditions and accentuating the necessity of checking the threatening economic collapse in order to save the only treasure of the German people, their good health. The existing economic conditions in Germany will destroy the health of the people and with this their capacity for work. The proclamation also announces a meeting on December 15th in Berlin University where the most eminent members of the medical world will present a picture of German distress. At this meeting several German physicians will speak on the subject of the sickbed of the German people.

THE CLASHING OF ECONOMIC AND SANITARY REGULATIONS.

The Board of Sanitation of Vienna has resolved to forbid automobile riding on Sunday in the environment of Vienna and to submit this resolution also to the provincial Prefecture of Lower Austria for the issuance of a similar order. The board was induced to do this by reason of the fact that automobiles caused such clouds of dust that the enjoyment of fresh air and sunlight were entirely impossible for children and foot passenger excursionists whose only recreation was coming to the suburbs. The organization of the Austrian automobile dealers has protested against this, arguing that it is not the proper way to make the air dust proof but is the proper way to ruin entirely the so nearly moribund Austrian automobile industry. The City Council of Vienna is called upon to solve a difficult problem.

PROSTITUTION IN VIENNA.

The City Council of Vienna publishes interesting statistical data relating to the spread of prostitution in Vienna. According to these data prostitution under control forms only an unimportant part of secret prostitution. While at the end of 1921 there were 1,438 secret prostitutes in Vienna in the course of this year the number of those caught on the street and in public bars amounted to 6,741 and even these represented only a small fraction of secret prostitutes evading control. The number of those under control decreased in proportion to that of prewar times. In 1913 the number of prostitutes in Vienna under police control was 1,879. Seventy per cent. of these were between eighteen and twenty-five years of age; 232 were over forty, fifty-seven were over fifty, and two were over sixty years of age. As to former occupation forty per cent. of the prostitutes had been domestic servants, thirty-six per cent. working women, thirteen per cent. waitresses and public bar cashiers. It is worthy of mentioning that the majority of working women had been only auxiliary laborers. Qualified working women represented only three per cent. It is noteworthy and characteristic of the social life of Vienna that in 1913 453 novices were registered at the police office; in 1914, 337; in 1915, only 78, and during the war this number decreased 48, while the distress after the war increased the number of novices to 538 in 1919 and in 1921 277 applied for "booklets" among those being 189 Viennese and 18 foreigners.

LENGTHENING OF HUMAN LIFE.

Dr. Paasch, secret counsellor in Berlin, has addressed an earnest warning to all German youths and their parents. He advises every family to compile its family tree, comprising all its members, and indicating what diseases each member suffers from. From this information Dr. Paasch wishes to be able to state, in cases of couples about to be married, whether or not healthy offspring can be expected. According to his opinion it is possible to lengthen human life but only through generations, and only then if healthy parents are engendering healthy offspring. He recommends children as well as parents to be careful in their manner of living. They should not overstrain themselves either bodily or mentally, should take care of their nutrition and clothing, and an adequate equilibrium between physical and mental work should be established. They should beware of sexual diseases and control their passions. They should take a sufficient amount of sleep because the most important requirement in long life was conserving the vital forces. However, all these factors came to expression only in the second and third generations and at that time very noticeable.

ADVERTISING THE NAMES OF DRUNKEN MEN.

The community council at Graz, Austria, has issued an order that the police shall compile a weekly list of those who have been arrested for drunkenness, this list to be printed and pasted on all poster columns. The first list appeared last week. The majority of culprits were industrial workmen, grocers, lower officials, laborers, and a few night watchmen. This radical measure will evidently decrease the drunkenness in the beautiful capital of Styria, which in season is crowded with English and American visitors.

COMPULSORY MARRIAGE IN ANGORA.

There is a measure before the Turkish National Parliament of Angora which in all probability will become a law. This proposed law provides that every Turkish youth eighteen years of age is allowed to marry and those who fail to marry before their twenty-fifth year can be compelled by state power to do so. The law does not show any mercy and if the party to be married is ill he will have to undergo a very rigid medical examination. If anybody is found fit for marriage, and despite this is not inclined to marry, he is regarded as a deserter and loses his passive electoral rights, cannot any longer fill a public official position and cannot even become an official of a private enterprise. If he has some annuities one quarter of these go to the state. According to these rules in the Angora republic single blessedness will become a luxury of the wealthy. The proposed law also protects the holiness of marriage. If the husband wishes to travel without his wife he has to get permission from the magistrate. If his journey lasts a long time he has to marry a second time and the wife obtained on the way has to be taken home. But not only a long journey entitles a man to more than one wife. According to this proposed law husbands who are fifty years of age, if their financial position permits, are obliged to marry another wife, otherwise they have to maintain young orphans. There is only one excuse for delaying marriage: students are absolved from marriage until the termination of their studies. It is easy to prophesy that in Angora there will be a good many students who will not make haste to finish their careers, and students of thirty-five and forty years of age will not be rare occurrences.

A PSYCHOANALYTICAL HOSPITAL IN VIENNA.

The first psychoanalytical hospital has just been opened in Vienna. Its chief object is to heal neurotic patients among the poorer classes and at the same time to give practical instruction to medical students and doctors in psychoanalysis. A similar institute was established three years ago in Berlin, to the entire satisfaction of the patients seeking aid, and it also has awakened the interest of medical men in the subject of psychoanalysis.

THE SALARY MOVEMENT OF THE VIENNA INSURANCE DOCTORS.

The Vienna insurance doctors were compelled to continue their strike on account of the disgracefully low salary they received from the insurance offices. The strike ended with their full victory. The unity of the doctors has been imposing. Workmen and laborers were unanimously supporting the doctors' interests.

CONDITIONS IN RUSSIA.

According to reports coming from authoritative sources there were 119,932 cases of typhus exanthematous cases in Russia in January, 1922, 180,285 in February, and 213,102 in March. In Ukrania five million people died of starvation; in Charkow, the capital of Ukrania, five hundred thousand out of a population of eight hundred thousand died as a consequence of famine. Out of these one hundred and twenty-five thousand from the first to the twentieth of March.

LONDON LETTER.

(From our own correspondent.)

LONDON, *December* 23, 1922.

THE COST OF SICKNESS.

A meeting was held in London recently by the Industrial League and Council at which Lieutenant Colonel F. E. Freemantle, M. P., spoke on the economics of public health. He said, in part, that in the promotion of public health the many intellectual and moral advantages resulting from health could not be represented in financial terms, and there was danger of necessary services being curtailed as if the moral values were of no importance. In certain other fields, such as in education and religious matters, for instance, this was even more serious than in public health, for in these spheres no material profit could be definitely shown as a result of suggested expenditure. In public health there was this advantage that there were definite material gains from wise expenditure which could be shown to be reduced by a reduction of that expenditure. Definite statistical proof could be adduced to show that the ascertainable cost of sickness and disablement to the community of England and Wales amounted to no less than £150,000,000 a year. To this should be added large sums which it was impossible to express in financial terms. Judging from the estimate of £94,000,000 as the loss from tuberculosis alone, the estimated loss of £150,000,000 from all forms of sickness would seem to be greatly underestimated. But during the course of the public health movement during the past sixty years the improvement in health had given a very large possible increase in output which, reckoned on the basis of lives saved and the average wages of an agricultural laborer, sixty years ago, worked out at £62,000,000; but reckoned from the increased expectation of life amounted to £200,000,000 a year, several times as much as the amount spent on maintaining the public health services. It could not be claimed that all the loss to the community from sickness and disablement could ever be abolished, or that the public health services could be materially, if at all, diminished, but a large amount of sickness and disablement was still preventable. As an instance of what might reasonably be expected in the prevention of sickness in the near future, the possible elimination of tuberculosis should add £4,700,000 yearly to the exchequer, and £94,000,000 to the national income. It was obvious, therefore, that any effective measures proposed for the reduction of tuberculosis would be financially justified if consideration be confined to the material profit and loss to the exchequer. Many measures put forward in perfect good faith by experts and the public were not yet sufficiently substantiated to merit their adoption as effective. Many were advocated too much from the viewpoint of those who sought to raise out of the exchequer the material comfort of workers. While improvement in feeding and other social conditions might be expected to diminish tuberculosis and improve health it might have a precisely contrary effect if the methods adopted tended to undermine initiative, morale, and personal care of the individual. It was imperative for medical officers of health and for the medical profession generally, as expert guardians of the public welfare, to stand between the public and the government, to recommend to the latter only such measures as could be proved to have value and in putting forward suggestions and hypotheses to be most careful in stating the limiting conditions.

DR. CAIUS.

The University of Cambridge is an excellent training school for medical students during their first three years of study. The teachers are all of high rank, headed by the Regius Professor of Physics, Sir W. Clifford Allbutt, perhaps the most cultured and all round physician of the world. The college of Cambridge University in which the majority of medical students are trained is Caius College. It is indeed the medical college. The name of the college is rightly Gonville and Caius after the founder of Gonville Hall, but it is now always known as Caius College. John Caius, the second founder, was born in Norwich in 1510. His name was Key or Kaye, Caius being the Latinized form. In 1529 he became a student of Gonville Hall and eventually became a Fellow. Later he went to the University of Padua, then a very famous university for the study of medicine. He made a tour of Europe and became an eminent scholar and physician. In due course he accumulated a considerable amount of money and in 1557 decided to refound Gonville Hall, Cambridge. He gave a great deal of money for this purpose and arranged that in future the college should be called Gonville Hall and Caius College. In an English university a college was of higher status than a hall and the advancement thus brought about was due to Dr. Caius. He was elected nine times in succession as president of the Royal College of Physicians in London.

SCIENTIFIC FEEDING OF ANIMALS.

The lower animals, as well as human beings, are now being fed on scientific principles, and from investigations in this direction it is apparent that valuable lessons will be learned with respect to the feeding and nutrition of the human animal. At the Rowett Institute, Aberdeen, questions of metabolism and digestion are being considered carefully from the point of view of farm animals. Although the matter is still in its infancy several important facts have been discovered already and in the course of time we may expect the principles to be expounded properly and lucidly. The object, of course, is to discover the metabolic balance and when this knowledge has been gained to make use of it in such a manner that horses and stock of every description may be fed more nutritiously and economically. The greatest progress has been made with pigs, so far as nutritious and economical feeding is concerned, and indeed the scientific feeding of farm animals appears to be very encouraging. The main features of these experiments which promise to be of value when applied to the metabolism and digestion of human subjects are that blood pressure can be more carefully studied and it is possible to explore further the question of rickets. Heat production in the animal system may also be studied through the respiratory organs, and it is anticipated that useful and valuable results will be obtained. It may be said that in some ways better results may be expected with animals fed scientifically than with human beings. In man suggestion has enormous influence over the body and of course the processes of digestion. Strong emotions play havoc with the digestion.

CANCER IN KENT.

The Medical Officer of Health for Kent, Dr. Greenwood, states in his annual report that the death rate from cancer in that county steadily increases. The total number of deaths from this disease in 1921 was the highest yet recorded and gave a rate of 1.33 for the whole county, compared with 0.90 in 1910, the increase being nearly fifty per cent. Dr. Greenwood says that in round numbers one person in every 780 died from this disease and only heart disease caused more deaths.

SMALLPOX IN LONDON.

There has been no fresh case of smallpox in London for more than three weeks and only twelve patients are now under treatment. In pointing out the continued need for vaccination, Dr. E. E. Scrase, medical officer of health for Hempstead, says: "Outbreaks of smallpox rarely occur without a preliminary period, such as the present. Thus in 1902 smallpox was simmering in London for practically a year before it assumed epidemic proportions, and in the celebrated epidemic of Gloucester in 1895 and 1896 it averaged three cases a month for six months and then suddenly burst out with 733 in the eleventh month." Smallpox is breaking out in different parts of Great Britain and the menace of an epidemic has by no means passed. The sinister features of the London outbreak have been the virulence of the type (it was imported from Asia) and the prevalence of unvaccinated individuals.

CHANGES IN THE BIRTH RATE.

Dr. Bonar presided at a meeting of the Royal Statistical Society held on the evening of December 19th at which a paper was read by Mr. T. P. S. Jastrzebski on changes in the birth rate and in legitimate fertility in London, 1911 and 1921. He said that at the date of the census in 1911 married women under forty-five in the county of London numbered 540,419, or 11.95 per cent. of the population; in 1921 they numbered 549,373, or 12.05 per cent. Other factors being unchanged there should therefore have been a rise in the birth rate of roughly three per cent. But the age grouping of these women showed considerable diversity and there had been, in fact, a decline in the birth rate and this decline was ten times greater than could be accounted for by the lower "force of issue" due to the variation in the age groups. Both in the crude and effective birth rates the change in the decennium had been in the direction of lessening the gap between the social classes. The declining infant mortality had naturally been more favorable to the poorer than to the richer districts. In London as a whole legitimate fertility fell by twenty-five to the thousand married women under forty-five, or 12.75 per cent. Both in the birth rate and in legitimate fertility there was a decline of about one per cent. per annum in 1911 and 1921. But there was no necessity to talk about dying races and nations as yet. The immediate problem of the future was not of under population but of over population.

THE CHANGING TYPE OF DISEASE.

Is disease changing its type? According to a London physician it is, and he went on to say that practitioners in many parts of the country had told him they could no longer easily recognize the textbook descriptions of the various maladies. Influenza is fairly prevalent in London and in the country generally, but it is of a different type from that usually met with. It is not of a deadly character but affects the nervous system profoundly. Deep depression is a significant feature and recovery is slow. However, influenza has in the past exhibited itself in protean forms and therefore can hardly be given as a good example of a changing character of disease. It is true that many of the textbook descriptions of disease are inaccurate and sometimes misleading and that emendations should be made in conformity with disease as it is seen today. It may be added that some of the best British textbooks have been thoroughly revised recently and at least one excellent new one has been written.

NEW SCHOOL OF PATHOLOGY AT OXFORD.

Sir William Dunn's trustees offered to Oxford University some little time ago the sum of £3,000 for the adaptation of the existing pathology school into a future school of pharmacology. This offer will be accepted, but it is also proposed that the new buildings shall be erected in the parks. Opposition is being organized to the section of the proposed statute which provides for the building of the new pathology school in the parks.

LEGACY FOR NEW CHAIR AT GLASGOW UNIVERSITY.

Mr. William Gemmell, only brother of the late Professor Samson Gemmell, a noted surgeon and a professor of Glasgow University on the medical side, died recently in London and his will provides for £20,000 being devoted to the establishment of a new chair of medicine or science at Glasgow University.

OXFORD PROFESSOR WINS NOBEL PRIZE.

Professor Soddy has brought distinction to Oxford University by obtaining the Nobel Prize for Chemistry for 1921, for his work on the chemistry of the radioactive elements and the nature of isotropes.

POISONING AND DEATH CERTIFICATES.

Sir William Wilcox, the poison expert and medical adviser to the British Home Office, addressing a meeting of cremation authorities at the Guildhall, London, recently, criticized the present system of granting death certificates as an insufficient safeguard against cases of murder by poisoning. The statement was made in connection with a discussion as to whether cremation helped to conceal crimes of this character. At present, according to Sir William, the system of granting death certificates is extremely lax. They were sometimes filled up in a casual way before the doctor had satisfied himself as to the fact of death. There were numerous instances in which certificates were granted before the persons were dead. He asserted that the records of notable crimes, which would not have been discovered but for some fact brought to light after burial, illustrated the weakness of the death certificate system. If it were revised there would not be so many exhumations as at present and concealment of crime would be impossible. Medical practitioners were cautioned against filling in death certificates without an examination of the body and in each case there should be a consultation with other doctors. It was obvious that cremation would remove all traces of poisons such as arsenic, hyoscine, or strychnine, but the possibility of concealment of crime was largely guarded against by the formalities that had to be observed before cremation could take place. Two death certificates had to be given, one by an ordinary practitioner and one by a specialist.

MEDICAL MEN IN POLITICS.

Medical men in the present parliament number about the same as in the last. Ten were elected while thirty or thereabouts offered themselves for election or reelection. There was somewhat of a slaughter of the innocents—medical men in politics in this country are not only a negligible quantity, but an unknown quantity. No less than nine medical men stood as labor candidates. Perhaps it would be unjust to term them wolves in sheep's clothing, the reverse denomination might be more applicable—sheep in wolves' clothing, as sad to relate, the labor party here is more than tinged with communism, Bolshevism or whatever it may be called. The red flag has been flaunted a good deal of late, although it is said of the labor party that the tail wags the dog, that is, the extremists, the majority of whom are not English or Scotch, sway the policy. Of the nine medical men who offered to represent labor in parliament one was returned for a London borough. Dr. Salter, the man in question, is said to be a particularly brilliant man who has devoted his life to the welfare of the poor and from a material point of view has sacrificed his career to this cause. Of the medical men ousted the best known is Dr. Christopher Addison, appointed by Lloyd George the first minister of the newly established Ministry of Health. Dr. Addison fell from grace, but instead of taking the castigation in a humble spirit, he rebelled, and when the election came on presented himself as a candidate under other colors. He was rejected. A medical man who came to grief at the polls was Dr. Wansey Bayly, a somewhat frequent contributor to your journal. Dr. Bayly had the temerity to oppose Lady Astor in her stronghold of South Plymouth. Lady Astor was too strongly entrenched and the attack was fruitless. It may be said that women in this election had very bad luck. Lady Astor and Mrs. Withringham, both sitting members, were the only ones returned, and, of course, no doctor of the three or four female members of the medical profession who stood were successful. Sir William Watson Cheyne, the great surgeon friend and pupil of Lister, who sat for the Scottish Universities, retired in favor of Sir George Berry, F. R. C. S., who was elected. Dr. Nathan Raw, a well known authority on tuberculosis, who was chairman of the medical group in the last parliament, retired owing to his appointment as Lord Chancellor's visitor in lunacy in succession to Sir James Crichton-Browne. Of the new members Sir Sydney Russell Wells is the most distinguished. Prior to representing the University of London in parliament he represented, and still represents, the University on the General Medical Council, has been a member of the University Senate for twenty years, and has recently resigned the Vice-Chancellorship. Sir Sydney is an authority on the heart and contributed a splendid article to our special heart number. He is a good organizer as well as a man of culture. He is engaged in postgraduate teaching. It is a matter of some interest to know that H. G. Wells, the celebrated novelist and economist, contested the University of London in the labor interest. Mr. Wells was at the bottom of the poll. A distinguished medical member reelected without opposition for Queen's University of Belfast, was Sir William Whitla, the noted therapeutist and pharmacologist. It will be observed that Queen's University, Belfast, still has representation in the British Parliament, while Dublin University has not.

DEATH OF SIR NORMAN MOORE.

Sir Norman Moore, M. D., LL. D., Camb., F. R. C. P. Lond., F. R. C. P. Ireland, consulting physician and emeritus lecturer on the principles and practice of medicine at St. Bartholomew's Hospital; late president of the Royal College of Physicians of London, died at the age of seventy-five on November 20th last. During his entire career he was closely connected with St. Bartholomew's Hospital, and for nineteen years resided within its walls. Although he held many important medical posts, it is as a medical historian that he will be remembered.

Book Reviews

BIOLOGICAL PAPERS.

Treballs de las Societat de Biologia. Aug. sete, 1919. Publications del'Institut de Ciencies. Publicats sota la direccio de A. Pi Suner. Barcelona: Institut d'Estaudis Catalaus, 1919.

Thirty-five papers were read before the Biological Society of Barcelona at its various sessions during 1919, the transactions being as usual published in Catelan Spanish. The society has at present forty-seven active members, of whom twenty-five prepared papers alone or in collaboration. The subjects show notable variety and some of interest to the clinician are devoted to spirochetosis, utero-hemorrhagica, gas gangrene, syphilis, tetanus, spastic paraplegia, anaphylaxis, the peptone treatment of infections, influenza, pyocyaneus infections, and glycosuria. Others deal chiefly with problems of embryology, physiology, and biochemistry. The most significant article deals with the intratracheal injection of antipneumococcus and antistreptococcus serum in the pulmonary complications of influenza by Bossan. The author punctures the larynx and throws the serum directly into the trachea. He relates five cases in which the treatment caused a brusque defervescence. In two others the patients were in extremis. In the other eight the patients recovered but the author does not regard the cases of crucial importance, for they would doubtless have recovered in any case.

HEMORRHOIDS.

Das Hämorrhoidalleiden. Wesen, Ursachen, Klinische Bild und Therapie. Von Prof. Dr. Boas. Mit einer Abbildung im Text and sechs Abb Abbildungen auf einer Tafel. Halle a.S: Carl Marhold Verlagsbuchhandlung, 1922.

In the present monograph Professor Boas gives an excellent picture of the hemorrhoidal affections and their management. Among other important items Boas minutely describes his new method of abolishing piles by injections of alcohol. The method consists in producing first anesthesia of the anal region, then exposing the piles by means of a suction cup and injecting 0.5 to 1 c. c. of ninety-six per cent. alcohol into each hemorrhoidal tumor. Petrolatum is then put over the entire anal region and all the nodes pushed back into the rectum. The patient is kept in bed from four to five days during which period recovery takes place. The monograph deserves to be read by every practitioner who will find many valuable hints in the treatment of the above malady.

LABORATORY TECHNIC.

Untersuchungen über den Athergehalt in Blut, Milch, Harn und Expirationsluft bei Chirurgischer Athernarkose sowie über Narkoseazidose. Von Karl Gramën. Acta Chirurgica Scandinavica, Supplementum I. Aus der Chirurgischen Abteilung des Maria Krankenhauses, Vorstand Doz. E. Key, Stockholm. Stockholm: Centraltryckeriet, 1922. Pp. viii-146.

The author found the investigations conducted heretofore on the ether content in the blood, milk, urine, and expiratory air after surgical ether anesthesia incomplete and therefore conducted a series of experiments to determine these facts in a material of fifty patients (surgical, gynecological and obstetrical) as follows: He made quantitative determinations of the ether content of the venous blood, both during and after the anesthesia and during the socalled period of elimination of the ether in the urine and expiratory air, respectively; of the transition of the ether into the mother's milk and from the maternal blood into that of the fetus, and also of the ether inhaled unwittingly during the anesthesia by the anesthetist and the other surgical attendants.

The tests given also include the usual ether anesthesia in different kinds of patients, the socalled ether-rausch with different methods of the administration of ether and of ether plus oxygen anesthesia. Observations were also made on the drop method of administration and many good hints as to the technic are recommended for practical application.

In his investigations on acidosis following anesthesia, the literature is reviewed and special credit is given to the work of the American authors. The symptomatology, predisposing factors, prophylaxis and therapy, particularly the latter, both preoperative and postoperative, are given. Quantitative estimations of the total acetone and of B oxybutyric acid in the blood and urine after ether anesthesia and qualitative estimations of the acetone and diacetic acid in the urine were made. In conclusion, the author mentions some general points on the use of purgation and starvation before and after operation.

Taken by and large, this little monograph is an excellent publication, dealing with the theory and practice of ether anesthesia. A bibliography is appended.

PSYCHOLOGY AND SOCIOLOGY.

Psychoanalyse und Sociologie. By Aurel Kolnai. Internationaler Psychoanalytischer Verlag, Leipzig, Vienna, Zurich, 1920. Internationale Psychoaneslytische Bibliothek, No. 9. Pp. 152.

One need not agree with all the conclusions drawn by this author in regard to present sociological conditions. Yet one will find his book provocative of thought to such an extent that one will consider carefully his interpretative suggestions concerning the movements of the day. He first states instructively the relation which psychoanalysis as a psychology dealing with the individual has toward the more broadly directed science of sociology. Both must work toward the same final purpose. Both must come to an understanding of society in its historical development and in its present tendencies through the understanding of the individuals who compose society. Through them alone social institutions have arisen. Moreover the end of both methods of approach is the fitting of society and the individual into an adaptation which is based upon this knowledge of individual psychology and the relation of the social elements to the social whole.

There is first a review of the principles of psychoanalysis and its discoveries in regard to the individual constitution and to his adaptation or nonadaptation to society. This is followed by a fuller discussion of the analysis of present tendencies in society chiefly the communist movement and the anarchistic attitude. These are studied from the point of view of the infantile family complex and are found to follow out those patterns which Freud has pointed out in his *Totem and Taboo.* The study of these movements as regressive phases of particular forms presents stimulating questions for further analytical thought. They are shown to reveal the efforts made to solve the conflicts represented, either by a new progressive solution or by the slipping into regression. One will be moved to inquire of oneself and of the author in how far reader or writer is moved by his own emotional attitude toward a definition of these things in terms of the infantile conflict. For these questions are closely woven in the fabric of the life of today. Yet one is led to a profound consideration of these movements which is both illuminating and stimulating for sociological understanding. Moreover, one can be only wholesomely stimulated personally by contemplating in these problems those individual unconscious features which move society either toward new constructive action or which distort reason to serve overwhelming emotional attitudes.

GYNECOLOGY.

Clinical and Operative Gynecology. By J. Munro Kerr. London: Oxford Medical Publications, Henry Frowde and Hodder Stoughton, 1922. Pp. xvi-832.

This book is the result of an attempt to present the subject of gynecology in a clinical form, but it is by no means an exhaustive treatise nor is it intended to be so. It is divided into three parts: clinical gynecology, medical treatment and remedies, and operative gynecology.

The first section contains numerous, condensed case histories. Only a brief summary of the normal anatomy is given. A novel feature in the chapter on the examination of the patient is a tabulated and illustrated account of the lesions possible. The discussion of the endocrine glands is included in the chapter on the physiology of the female reproductive organs. The functional disorders are given more than the usual amount of attention. The nervous disorders of females are exhaustively discussed by Ivy Mackenzie. The development and malformations are treated collectively by T. H. Bryce. The venereal diseases, gonorrhea and syphilis and their complications, are covered by David Watson. A special chapter is devoted to the abnormal conditions in the urinary and intestinal tracts, which may simulate diseases of the female reproductive organs. Throughout the first part of the book, the gross pathology of the various diseases is given full consideration, but the details of the microscopic appearances and characteristics are omitted, as the book is intended merely for those interested in the clinical side of gynecology.

The second part deals with the medical treatment of gynecological diseases, both general and local. The author is not enthusiastic about ionic medication, which is described in the words of Samuel Sloan, nor is he enthusiastic about the different electric modalities. He considers x rays as the most important remedy in gynecology. Radium and its emanations he uses only in advanced cases of carcinoma and in operable, foul cancers as a preliminary and preparatory agent for surgery. Little importance is attached to local douching and vaginal tampons. He deprecates curettage in endometritis and extols the value of cauterization and disinfection of the uterus.

The third part includes the details of technic in the preparation of the patient, the paraphernalia and the attendants and some remarks on anesthesia by J. Pation Boyd. The author's experience with spinal analgesia was uncertain; sacral analgesia was not used and local anesthesia was used only for minor perineal and vaginal operations. The postoperative complications and their treatment are discussed in full. Blood transfusion and its technic are discussed by W. Rankin. Special chapters are devoted to the minor operations, operations for the correction of uterine displacements, operations on the uterus, plastic operations for malformations, operations on the ovary, the urinary tract and on the appendix and intestines, respectively. This part of the book may well serve as an atlas of gynecological surgical procedure, as each step is indicated by illustrations opposite to the verbal description. The illustrations, with the exception of twelve excellent colored plates, consist simply of line illustrations. This work is a reflection of conservative English gynecology.

MATERIA MEDICA.

The Eclectic Materia Medica, Pharmacology and Therapeutics. By Harvey Wickes Felter, M.D. Forty-eight full page half-tone plates. Published by John K. Scudder, Cincinnati, Ohio, 1922. Pp. 702.

This is one of the most complete and comprehensive books on materia medica which has yet appeared outside of the dispensaries. It shows a very intimate knowledge of almost every phase of materia medica, but is strongly colored with the author's own predilection for the specific medication of the eclectic school of which he is one of the leaders. In spite of his eclectic views, which he frankly avows, the work contains a great deal which would be of interest to every physician and which it would profit most physicians to study. The author is well versed in the history of the indigenous materia medica. Dr. Felter brings to the task of bookmaking a ripe experience as a practitioner, as an editor, as a teacher and as an author, and presents in this volume a work which is probably the most valuable contribution to materia medica which has been made by the eclectic school.

UROLOGY.

Propedeutique et Technique Urologiques. Avec 153 Figures. Bruxelles: Goemaere; Paris: Masson & Cie, Editeurs. 1922. Pp. 483.

The author has dedicated this volume to the memory of Guyon, Nitze and Albarran, and we feel, after a careful perusal of its pages, that it is quite worthy of these master urologists.

From a practical viewpoint the book is full of urological meat, so to speak. Every phase of diagnostic technic is considered fully and clearly. Beginning with the examination of urine and of the genital secretions, the author considers instrumentation, asepsis, urological anesthesia, urinary tests, the bladder, ureters and kidneys, as well as the technical examination of the prostate, seminal vesicles, vasa deferentia and epididymes.

There are additional chapters on urinary symptomatology in general and a most interesting discussion of biological products in the diagnosis of urological conditions.

The French reading physician will find a fund of information between the covers of this volume; much to our regret, we do not know of any book in English that can be compared with it.

EYE REFLEX.

Untersuchungen uber die eigenreflexe (sehnenreflexe) menschlicher Muskeln. Von Paul Hoffmann. Berlin: Verlag von Julius Springer. 1922. Pp. 106.

This study of the tendon reflexes, or as the author calls them, autogenous reflexes, deals with methods of examination, mechanical, electric, and special, as well as with the nerve paths of excitation and inhibition. His conclusions support the view of Exner that these reflexes act as a protective mechanism by maintaining a joint position whenever a rapid change takes place in that position against the will of the subject. The studies were carried out not only on the extensor muscles of the foot but on the musculature of the arms as well, and contain a great deal of interest to the neurologist, the clinician, and the student of physiology.

STEKEL.

Psychosexueller Infantilismus (Die Seelische Kinderkrankheiten der Erwachsenen). Von Dr. Wilhelm Stekel. Berlin and Vienna: Urban & Schwarzenberg, 1922.

Among the subjects considered are Rejuvenation (referring to the longing for past youth), Urinary and Anal Sexuality, Zoanthropy and Zöophily, Pedophily, Gerontophily, Exhibitionism, Narcissism, Mysophily, Attacks of Rage, the Eternal Nursling, the Eternal Boy and Girl, and various other behaviors and types of men and women who literally "never grow up" in certain directions. Among the laity "people who never grow up," "big overgrown boy" men and the like are usually lovable characters, but in Stekel's book the youthfulness is not open—it is marked under vices, fanaticism and criminality and other abnormalities. Much of the subject matter, if not most of it, is usually discussed under sex perversions (not meaning inversion, for homosexuality is omitted throughout). The book is volume five of the author's *Störungen des Trieb-und Affektlebens.*

DIAGNOSIS.

Lehrbuch Klinischer Diagnostik und Untersuchungsmethodik für Studierende, Medizinalproktikanten, und Aerzte. Von Prof. Dr. Theodor Brugsch, Oberarzt d. H. Univ-klinik, Berlin, und Prof. Dr. Alfred Schittenhelm, Direktor d. Med. Klinik, Kiel. Fifth Edition. Berlin and Vienna: Urban und Schwarzenberg, 1921.

The present volume comprises 968 pages and 418 text figures. In their preface the authors style the late war and reconstruction period "the revolution." The work appeared originally in 1908, the third edition just before the war, and the fourth in 1918. The size has undergone but little change since the first appearance of the work. The postbellum era has seen a reawakening scientific ardor and the authors have given their readers the full benefits of electrocardiography and abdominal röntgenography. Other advances are in the application of micromethods to diseases of metabolism and a revision of the symptomatology and diagnosis of uterus. The Aschoff school is followed in dealing with tuberculosis.

PRIMITIVE.

Batoula. By Réne Maran. New York: Thomas Seltzer, 1922. Pp. 207.

Batoula, a novel by Réne Maran, a full blooded negro, was one of the literary sensations of Paris in 1921, the year of its publication. Its author was the recipient of the Prix Goncourt. Although the book is doubtless epoch making in the literary history of the African as the best work of fiction as yet produced by a full blooded negro, it seems hardly worthy, judged from unbiased literary standards, irrespective of the racial element, of the great sensation it created in France or of the high honors bestowed upon it. The narrative is too unproportioned and too sketchy to be high art in fiction. The book consists of a series of pictures of the life of Batoula, an African chieftain of the French Congo, ending with his death from the blow of a panther's paw. The much discussed descriptions of the Feast of the Circumcision and the Dance of Love contain nothing new to those who are conversant with symbolism and folk lore, although there may be a certain element of value in these scenes as portrayed by a member of the race itself, nearer to the heart of the people than others could be. The characters are drawn sincerely and without prejudice on the part of the author, but the vivid and dramatic style gives the book its greatest claim to literary value. Its real value, however, lies in its sociological significance as a poignant and unbiased picture of racial interactions, with suffering and tragedy on both sides, especially for the downtrodden black man.

LOYALTIES.

Loyalties: A Drama in Three Acts. By John Galsworthy. New York: Charles Scribner's Sons, 1922. Pp. 110.

Loyalties, now being played by an excellent English company, is so far the outstanding theatrical production of the season. The play is not only a masterpiece of dramatic art, but a most subtle and revealing study of individual human nature and group psychology. The author shows himself to be the keenest of analysts in his understanding of the motives guiding human conduct. The motif underlying the action seems to be the proneness of most people to think and act, not so often from a sense of truth, or of the moral, ethical, or social aspects of a set of circumstances, but from certain affective responses to the situation, sometimes of personal and sometimes of group origin—call them loyalists, prejudices, taboo, or what you will—still they persist in a world just beginning to realize their existence (this realization is cleverly brought out in the lines of several of the personages in the play) as the prime motives of most human conduct.

De Levis, a Jew, "young, rich, and new," has succeeded in getting himself invited to a rather exclusive English house party. While a guest there, a sum of money is stolen from him, and the whole of the play is concerned with the reactions of the various characters to the situation caused by the theft. These reactions involve necessarily various mental conflicts; that of loyalty to client against loyalty to profession; of race against race; of friendship and social "set" against an outsider; of varying standards of social behavior; of the love of a wife against a suspicion and subsequent knowledge of her husband's guilt; and of the husband's effort to live up to that love against his cowardly desire to run away from an entangling net of circumstances, which culminated in his escape from reality through suicide. The portrayal of this young officer, charming, popular and a daredevil in physical courage, yet a mental and moral weakling in the face of the less sensational realities of life, proves Galsworthy to be as keen an analyst of some of the pathological phases of human conduct as of its more normal manifestations. To the observant student of human nature, the real character of Captain Dancy, retired, winner of the Distinguished Service Order, is most subtly and cleverly revealed continually throughout the play, from the first mention of him making wild jumps as parlor "stunts" at the houseparty for a bet to help compensate for heavy losses just suffered at the races, to the pitiful note left when he shot himself. "It's only another jump," he said, and, even in the end unwilling, or unable, to face realities, he shifted the blame for the tragedy upon his friends—"A *pistol* keeps faith." There is no more vivid picture in modern literature of maladaptation and its often tragic consequences.

"Mere 'loyalty' is not enough," Galsworthy seems to tell us through almost every line of this understanding drama of human life. "What else is necessary?" Some day perhaps the physician, the psychologist, the sociologist, and the statesman, working together, will answer.

◆

Medicoliterary Notes.

In the recently issued annual report for 1921 of the Montclair Board of Health, it is recorded that there was an entire absence of smallpox in Montclair during that year. In contrast to this record the disastrous experience of Kansas City, Missouri, during 1921 is quoted: "Nearly a thousand cases of smallpox were reported during the year, and it is entirely probable that there were as many more mild unreported cases. The loss to business and to Kansas City's reputation can be expressed only in terms of millions of dollars. When several hundred thousand persons had been vaccinated, the epidemic stopped, because in a vaccinated and therefore protected community, there is no fuel on which the smallpox can feed. The cost of vaccinating Kansas City's people was several hundred thousand dollars. This amount of money pales into insignificance when it is compared with the suffering that the disease cost and the millions of dollars' damage done to business. How much better it would have been for the people to have been vaccinated before the epidemic came!"

* * *

A recent bulletin of the New York City Department of Health describes improvements in the hospital service of the department within the last few years. The report says: "In medical progress, the hospital work shows at least two noteworthy improvements. First is the care and hygienic education of women prisoners committed from the courts to the custody of the department of health's hospitals for treatment of venereal diseases. The far-reaching, good effect of this procedure cannot be overestimated. Second, drug addicts, having reached such a stage of degradation as actually to become a menace to the weakminded and young in the community with whom they come in contact, their disease was declared to be a pestilential one and the department of health proceeded to make, in Riverside Hospital, a place of treatment where the addicts could be effectually taken off the drug."

* * *

Summer Play Schools in New York City is the title of an article in *School and Society* for October 14th by Mary G. Armstrong.

* * *

The *Atlantic Monthly* for December contains, among other articles of interest, The American Jail, by Joseph Fishman.

* * *

A recent number of *Epidemiological Intelligence,* published by the health section of the League of Nations, quotes statistical information about the depopulation of Russia during recent years. Of all the causes to which this is attributed, epidemic diseases have caused the greatest loss of life. The following causes are given for the decline in population: 1. Emigration following the civil war, estimated at two million; 2, military losses in the world war, two million five hundred thousand; 3, loss of life in the civil war estimated at one million; 4, excess mortality largely due to the great epidemics, estimated at, at least, three million five hundred thousand. Another statement of interest is that the birth rate, extremely high before the war, averaging forty-five to the thousand of the population, has declined by more than forty per cent.

* * *

Six Characters in Search of an Author, translated from the Italian of Luigi Pirandello, is one of the cleverest and most original plays now running in New York. Six characters have been created by a playwright, but abandoned when the latter found that probably no theatre could be found to carry out adequately the ideals upon which his prospective play was based. These characters appear at the rehearsal of another play and demand that the drama for which they were destined be presented. Pirandello's play is a satire upon the liberties taken by managers and producers with the conceptions of authors.

* * *

The October number of *Health News,* the monthly bulletin of the New York State Department of Health, is an issue of unusual interest. Among leading articles are The Layman in Public Health, by Dr. Livingston Farrand, recently elected President of Cornell University; Politics and the Health Officer, by Dr. Matthias Nicoll, Jr., Deputy Commissioner of the State Health Department; Problems of a Rural Health Officer, by Dr. Stanton P. Hull; and The Health Officers' Opportunity for Research, by Dr. Burdge P. MacLean.

Practical Therapeutics

ELECTROMAGNETIC WAVES AS A THERAPEUTIC AGENT.

An Appreciation of the Electronic Theory.

By C. Everett Field, M. D.,
New York,
Director, Radium Institute of New York.

SUMMARY:

A. That electromagnetic forces govern the transit of substances (electrons) making up elementary ether.

B. That the electronic theory of all matter permits the argument of an electromagnetic influence fostering the exchange of electrons.

C. That the physiological and biochemical functions of the human body in health depend notably upon the electromagnetic wave phenomena commonly described in the ionization and colloidal state.

D. That any departure from the normal condition of tissue, bone or fluid cell structures, calls forth an altered chemistry with consequent disordered and distorted process of autolysis.

E. That the pathology resulting can, and is, favorably acted upon by certain artificially induced electromagnetic forces of soft and minute wave lengths, to the extent that both autolytic and catalytic processes are stimulated.

F. That while the free exchange of artificial and normal electromagnetic wave influences within the body may not be proven physically, extensive clinical data support strongly the theory advanced.

In the *Boston Medical and Surgical Journal* of December 14, 1922, Dr. Bronson Crothers states: "Quite unconsciously the joy of discovery often forces announcement before the finders know exactly what they have found. The virtues of the effective pioneer rarely include reticence or understatement." I heartily agree with this statement, and holding it as a warning, have tried to summarize my report with at least a shade of conservatism. The abundance of clinical success with the electromagnetic wave therapy permits me to make a plain statement without much reservation. At the same time we must acknowledge that we do not know exactly what we have found, owing to a lack of laboratory check up. How far our future study of this type of physical force will carry us, we cannot tell; therefore, under the circumstances, we prefer to class this contribution as a preliminary announcement.

It has always been the hope of the practitioner that he could secure the aid of additional adjunct measures of treatment that would hasten the processes of resolution, aid in the reduction of congestion, edema, and pressure symptoms. Various types of physical therapeutics are therefore utilized in the ultrachronic conditions often referred for our special study.

Many of the long advanced cases of arthritis come to us with the causative features of their pathology well studied and remedied, but the results of the infection still remain, despite a long effort at treatment. In our opinion, drug therapy in such cases is of little value, and our attention for several years has been focused on all measures of physical therapy. Obviously the theme of arthritis involves the great question of disordered metabolism, and when one enters that field, he immediately opens the door to a host of other diseases that could be considered under the same study. Therefore, my statement will be generalized to cover varied types of cases that have been influenced.

Recognizing the value and limitations of vibratory force, high frequency current, and the ultraviolet ray in controlling muscle and nerve cell stimulation, and in exerting sedative and anodyne influences, we have been interested in securing modifications of the electrical current that would deepen wave impulses. Seemingly we have now secured a simple apparatus producing electromagnetic bombardment of the deep tissues, with wave currents of sufficient penetration to aid in the reestablishment of circulation and fostering the chemical processes of repair.

A full acceptance and appreciation of the electronic theory as represented in the ionization and colloidal state of the human metabolism, must be acknowledged as a basic fact. Furthermore, we must recognize that in a perfect state of health and under proper metabolism, with all the forces that influence its autolytic and catalytic processes, makes its chemical change under fixed conditions. Slight departure from the normal quickly influences body chemistry, and the movement of the electronic bodies of all types is interfered with. Any injury of the functions of any organs of the body calls on the reserve forces of other organs, tissues or fluids to aid in the repair. Interference with the circulation consequent to organic disease calls forth increased effort on the part of our reserve chemistry. Any material change in the chemistry of the fluids of the body at once call on the various glands that govern the chemical makeup of the body for increased service. In such conditions we look for aid to any force that may act to increase the normal chemical reserve of the body. We often find that certain agents act as synergists, in that they serve to increase or hasten normal chemical processes. In our opinion we have in certain modifications of the electromagnetic wave a force that is harmoniously received by the normal ionization processes, and which materially influences metabolic function. There have been many experiments to prove the response of electrons through the effect of a magnetic field and ample proof is forthcoming to show that the transmission of electrical oscillations secures its response in the electronic constituents of the human body to the extent that improved chemical processes are noted. In other words, it is possible to hasten the normal processes of both autolysis and catalysis by means of a properly modified electromagnetic current.

We recognize in our work with radium in diseases of faulty metabolism, that the tremendous energy of alpha and beta electrons exert a beneficial influence on account of their positive and negative electrical characteristics. Following the introduction of this force within the body, prompt and definite changes are noted in many of the processes of metabolic function. Studying quite intensively this phenomenon there was made apparent the similarity of the wave of electrons thrown out in the disintegration of radium and the positive and negative waves of electrons we find in the ordinary electric current. In the negative current we exhibit a stream of electrons moving actively on their course, and as a positive type, these electrons may appear as atoms with the nuclear element predominating. We agree fully with the theory that the entire human body is but the construction of an enormous laboratory functioning largely under electromagnetic influences. It is readily seen, therefore, that various physical agencies of treatment may tend to stimulate processes of healing and repair in conditions where drugs might be given with no power to reach the affected organ or tissue. With the truth fixed a study of the various means of transmission of electrical oscillations becomes interesting. The application of an alternating magnetic field should tend to stimulate peripheral and deep circulation to a varied depth and distance from the coil. Furthermore, when the impulses of the stream of electrons exerts its force upon the body electronic stream, the full extent of such transmission cannot be estimated correctly. The physiological changes made apparent in the clinical picture can be observed and reported upon.

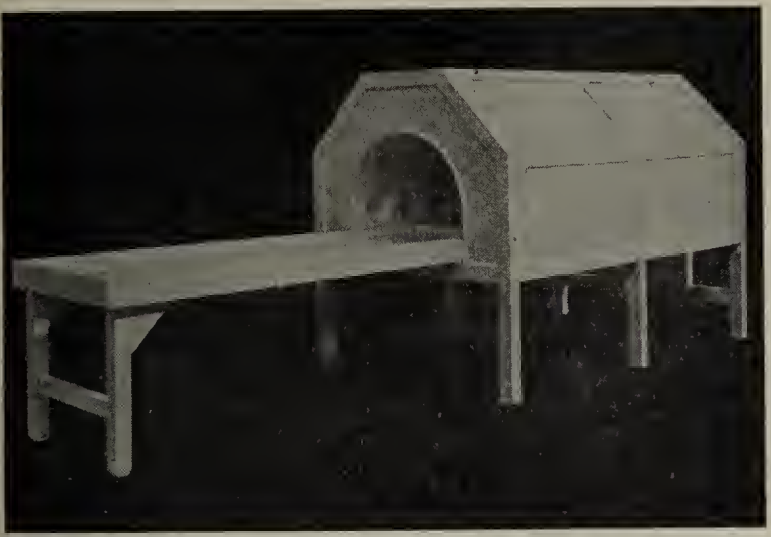

Fig. 1.—Apparatus used for treatment.

Early in 1922, Dr. Roland F. Wear, of Berwick, Pa., called to our attention his preliminary report on the use of a special coil which he had termed an electron emanator. This apparatus consisted of disc like plaques measuring about ten inches by an inch and a half each, made up of some seventeen hundred feet of insulated copper wire. This coil used single or multiple is applied and regulated under simple control of the operator, to permit the entire energy from a 110 alternating current, sixty cycle current, to be brought in contact with the patient, in close or distant range, varied as seems best indicated. The same current is used in conjunction with the thermic influences of the electric light cabinet in some of our experiments. The technic is simple and few contraindications are met. The single device weighs about fifteen pounds, and its weight is supported by special apparatus. As the rapid stream of electrons flow through the coil, there develops a form of vibration together with a gentle hum, noticeable, but in no wise unpleasant. After about sixty minutes of application, the coil becomes quite warm and may need additional padding or distance screen.

Certain physiological influences manifest during a series of treatments with the electron oscillator are evidenced directly on the tissue treated; on the eliminating organs and body chemistry. Probably the most pronounced single effect noted is the anodyne influence; almost any type of pain, that has come to our attention, has been markedly lessened or completely relieved. A distinct tonic effect is commonly met in a majority of the cases of our series, accompanied by a material increase in the erythrocyte count. Its application over areas of scar tissue and fibrous adhesion, such as are commonly met in the arthritis cases, tends to restore circulation and lessen rigidity. In our opinion the most startling effects have been met in ameliorating the pain met in our gynecological cases, particularly in those suffering either from malignant or benign conditions.

Among the benefits that may be derived from the electromagnetic wave phenomena are for the pains of all acute and subacute inflammatory processes. Pain associated with pressure symptoms, arthritis of subacute and chronic types, myalgias, pain associated with scar tissue formation or postoperative states, uterine and ovarian pain, neuritis, certain types of paralysis, pains associated with tabes, etc. From this brief outline many other indications will at once reveal themselves to the clinician.

The adaptability of the electromagnetic therapy as described awakens the possibility of a very wide field of application. While we are free in the opinion that this measure should be classed as that of an adjunct type of treatment, we will report a few cases wherein the electron emanator was the only means of therapy used.

Case I.—Mrs. M. G., aged thirty-nine, had been referred with a diagnosis of uterine carcinoma of the hopeless, inoperable, type. The pain was very severe, controlled only by three grains of morphine sulphate daily. The pain radiated anteriorly over lower abdomen and down the sides of the thighs; posteriorly, deep in the sacral region and following to the deep pelvic nerves. Application of the current, both anteriorly and posteriorly, in periods of one hour twice daily gave prompt relief. The administration of morphine was discontinued except the night dose of half a grain by mouth. The pain was controlled over a period of seven weeks of application.

Case II.—Mrs. J. C. L., a noninstitution case, aged forty-three. The diagnosis was dysmenorrhea, resulting from a chronic endometritis of nine years' standing, corrected three years previously by operation. Her previous condition showed marked retroflexion of the uterine body. She suffered terrific pain for ten days at each period during the past seven years. She was of the neurasthenic type, poorly nourished and a semiinvalid. During eight weeks of treatment, the electromagnetic current was administered daily for a period of an hour and a quarter, discs being placed on the lower abdomen and sacral regions, with fifteen minutes of rest midway between treatment. The pain was controlled at the first menstrual epoch to a short period of one hour's distress on the first day. No pain was evidenced during the second monthly period. An interesting feature was that the patient showed a gain of nine pounds in weight in two months. The blood count was as follows: October 23, prior to treatment, red cell count 3,600,000; on December 21st; the count represented 4,700,000. Marked general improvement was noted, the woman taking up all her household duties. During the fifty-two days of observation, treatments were made on twenty-eight days.

CASE III.—Mrs. J. C. M., aged fifty-four, suffering from multiple neuritis associated with mammary carcinoma (postoperative). She had been operated upon with complete removal of glands of left breast and axilla seven months previously. During the past four months she had suffered intensely from lancinating pains through left shoulder and extending down the arm, also from some intercostal pain running under the scapula. There was general tenderness of the tissue over entire left chest. The patient had refrained from using narcotics, but was meeting with poor results from forty grains of aspirin daily. First four applications of the electron oscillator gave little effect, the discs being used single in each area with forty minute periods. Following the application of twin coils with sixty minute application relief of pain was effected within fifteen minutes of start of treatment. Complete relief during the first ten days thereafter lasted each day about ten or twelve hours. After five weeks of treatments (every other day) the pain was practically gone. During the last week of treatment the pain was evidenced but once and then for a few moments only.

CASE IV.—Mrs. A. N. F., aged fifty-two. The diagnosis was chronic progressive arthritis, all joints affected, some enlarged to twice their normal size. The condition had existed a year and a half. She was lifted out of bed each morning and remained in a wheel chair all day. There was complete atrophy of the muscles with hamstring contractions. She was classed as an "impossible case" and referred for radium therapy. The pain was so severe, especially where hamstring contractions prevailed, that radium treatment was deferred. The chief seat of pain was down the back of the thigh, across the shoulders, and along the muscles at both sides of the neck. Electromagnetic current was applied forty minutes daily on three separate areas for fourteen successive days. Gradual relief of pain was experienced with definite but limited restoration of motion reported. Three weeks of treatment gave complete relief of pain except that shown on forced motion. Radium therapy was then instituted with continuation of electric vibration. The patient gained five pounds in weight during six weeks of treatment as indicated prior to the adoption of radium treatment.

CASE V.—Capt. J. E. A diagnosis had been made of Raynaud's disease following frozen finger tips on both hands during aeroplane flights in France in 1917. There developed an endarteritis obliterans, with tendency toward gangrene, and loss of sensation at tips of fingers with extremely poor circulation. During the winter months the tissue of the entire hands showed capillary circulation blanched out with weak white skin. Heat, various types of electric vibration, and massage were used by reconstruction hospital with no permanent service. Admitted October 12, 1922 and placed on weekly treatments with the combined crossfire energy of two coils of the electron oscillator. Six applications resulted in markedly dilating the terminal capillaie, with consequent improvement in sensation. Ulceration at tips of fingers healed and apparently a permanent clinical cure was obtained.

323 RIVERSIDE DRIVE.

Case VI. will appear in the author's reprints.

NONSURGICAL TREATMENT OF INTERNAL HEMORRHOIDS.

By CHARLES D. AARON, M. D.,

Detroit.

The following cuts were inadvertently omitted from the paper on the Nonsurgical Treatment of Internal Hemorrhoids, by Dr. Charles D. Aaron, which appeared in the NEW YORK MEDICAL JOURNAL AND MEDICAL RECORD, for December 20, 1922.

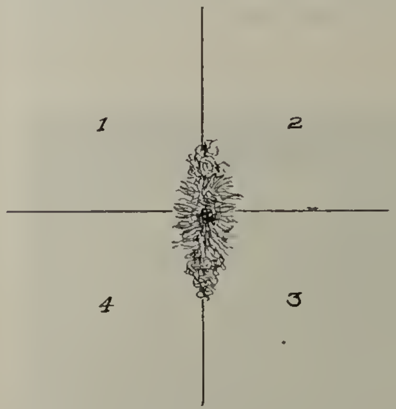

FIG. 1

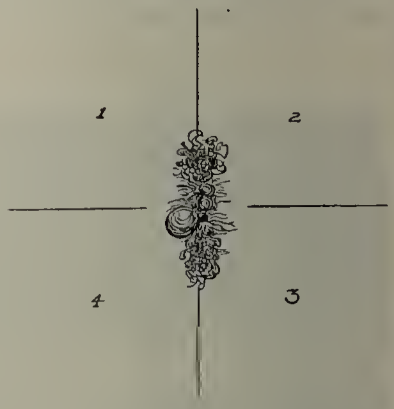

FIG. 2

FIG. 1.—These are imaginary lines, dividing the anal region into four areas (quadrants), as an aid to the operator in injecting these areas in succession until the entire region is treated. It is important that the picture of these imaginary lines be fixed in the operator's mind, and that a record be kept of the first quadrant injected, or as each quadrant is injected—for it may not always be advisable to begin with No. 1. The most troublesome hemorrhoid may require first treatment. When, however, the case is one that simply requires obliteration of hemorrhoidal veins throughout the whole extent of the rectal lumen, the injections may proceed in numerical order from quadrant No. 1 to quadrant No. 4. The patient's right anterior anal quadrant is No. 1, the left anterior No. 2, the left posterior No. 3, and the right posterior No. 4.

FIG. 2.—Protruding internal hemorrhoids.

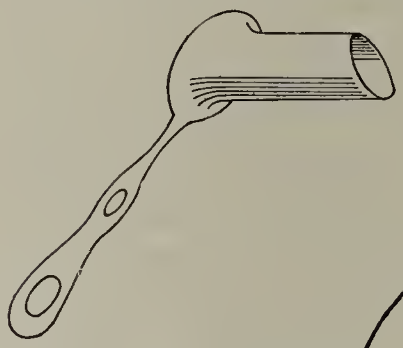

FIG. 3.—Oblique anoscope without obturator. The use of this instrument confines the field of operation to the quadrant to be treated and makes the insertion of the needle in the proper place a very simple matter, as shown in Fig. 4.

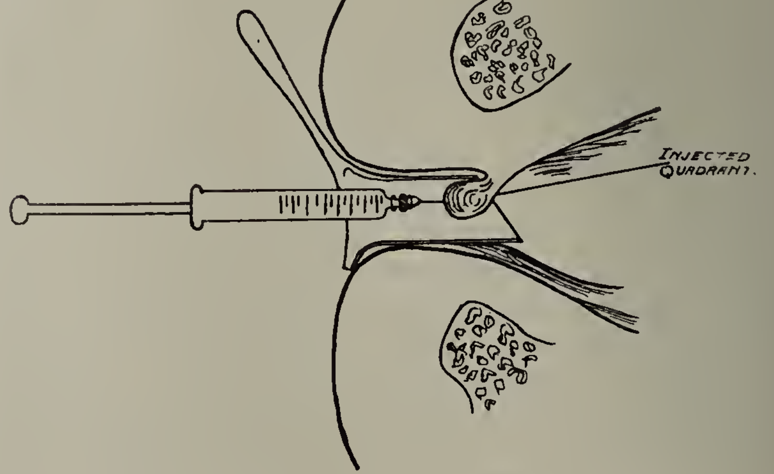

FIG. 4.—Needle introduced in centre of quadrant.

Proceedings of Societies

SOUTHERN MEDICAL ASSOCIATION.

Sixteenth Annual Meeting, Held at Chattanooga, Tenn., November 13 to 16, 1922.

The President, Dr. Seale Harris, of Birmingham, Ala., in the Chair.

Malaria in Children and the Abuse of Quinine.—Dr. Eugene Rosamond, of Memphis, Tenn., stated that the laboratory test for malaria was reliable in practically one hundred per cent. of cases. The incidence of age did not affect the clinical course of malaria. The abuse of quinine in overdoses to children was almost universal throughout the South. The giving of quinine in sugary syrups to infants and children with gastrointestinal diseases might aggravate the existing condition. The giving of overdoses of quinine might account for many nervous phenomena not explained otherwise.

Septic Meningitis in a Five Year Old Child.—Dr. W. A. Mulherin and Dr. V. P. Sydenstricker, of Atlanta, Ga., said that septic meningitis due to organisms resembling streptococcus viridans, but differing very much in growth, morphology and toxic properties, was observed in this five year old child. The primary focus of infection probably was the tonsils. The root of infection probably was through the lymphatics and not hematogenous. There was excessively high fever, 113° F., when bronchopneumonia became superimposed. There was localized encephalitis in the area of red nucleus, probably contributing to the height of the fever. Patient's blood agglutinated offending organism in dilution one to forty, showing acquired immunity. More general and scientific work and study should be given septic meningitis cases. If such was done, more definite specific knowledge would be obtained, which would help to lower its excessively high mortality.

Practical Points on Purgation.—Dr. Lewis W. Elias, of Asheville, N. C., stated that the alimentary canal was an absorbtive organ, the kidneys doing the elimination from the body tissues. Merely because the patient was sick was no reason for a purge. Most patients were best helped by water, food, and such hygienic measures as tended to build up resistance. If the lower bowels needed emptying, it should be done with an enema. This procedure was in line with the best thought of the time, but we were unconsciously influenced by long established custom.

High Voltage X Ray Therapy: A Six Months' Experience.—Dr. Sherwood Moore, of St. Louis, Mo., said there was no inherent superiority in so-called high voltage x ray therapy over the older methods and over the employment of radium save that it was far more efficient. Experience in treating 214 cases over a period of six months would indicate that the earlier of these cases derived sufficient benefit to make this the therapeutic agent. Even in advanced cases the relief of pain and the sometimes astonishing subjective improvement brought about by this method of treatment would indicate its application regardless of the hopelessness of effecting a cure.

Sectional Feeding.—Dr. A. J. Waring, of Savannah, Ga., stated that our general methods of presenting dietetics to the laity were possibly not wholly perfect. Sectional variations in diet, often confusing to the mother, were explainable and avoidable. The Southern pediatrist had his own very particular and very difficult problems in dietetics to handle, influenced markedly by local conditions.

X Ray Versus Radium in the Treatment of Uterine Hemorrhage.—Dr. Jackson W. Landham, of Atlanta, Ga., said that surgical treatment of uterine fibroids and myopathic bleeding was indicated in a very limited number of cases. An accurate diagnosis which might demand a preliminary curettage was absolutely essential. Since uterine hemorrhage might be controlled without producing a premature menopause, age did not necessarily constitute a contraindication to radiotherapy. Women with undeveloped sexual functions, pelvic inflammation, cervical or uterine polypi, pedunculated or degenerating fibroids, malignancy of the body of the uterus or large adherent fibroids producing pressure symptoms, should be treated surgically. Statistics and his personal experience with x ray and radium convinced him that röntgenotherapy was the method of choice in the management of these cases, except in patients who had marked hemorrhage. These should be treated with x ray and radium so that a quick result might be obtained. The technic he suggested contemplated a gradual menopause so that the unpleasant symptoms, characteristic of this period, might be prevented as much as possible.

A Few Points in Radiotherapeutic Technic of the Face and Mouth.—Dr. Walter A. Weed, of Birmingham, Ala., stated that in the treatment of epitheliomata involving the margin and mucous membrane of the eyelid, he cocanized the eye, covered the eyeball with a suitably designed piece of lead covered with rubber, and everted the eyelid if necessary by means of adhesive plaster, a stitch, or a pair of chalazion forceps, and treated intensively. Likewise, lesions of the inner canthus might be given treatment just as intensive as desired without danger to the eye itself or to the surrounding tissues. Lesions in this location were nearly always of the basal cell type, and in most instances amenable to radiotherapy. It was preeminently the method of choice because of its efficacy, and the unapproachable cosmetic results. The question of choosing between x ray and radium was largely one of convenience. Everything else being about equal, he usually employed the x ray because of the time saving factor. Another class of lesions that were often maltreated or untreated was malignancies of the lip, and especially of the inside of the mouth.

Group Medicine: A Critical Survey.—Dr. Warren T. Vaughan, of Richmond, Va., stated that group practice was a distinct advance in clinical medicine. It was not without its shortcomings and these should be recognized and remedied, if possible. Most of the discussions of group practice so far had either been laudatory by members of groups or condemnatory by nonmembers. We had now reached a stage where members of groups, who from their experience were best able to recognize the weak points and shortcomings of the system, should air these disadvantages and attempt to remedy them. Group practice in some form had come to stay. It was the duty of the profession who were interested in the work to devote their energies to establishing the most satisfactory form.

Treatment of Arterial Hypertension.—Dr. Ralph N. Greene, of Jacksonville, Fla., stated that hypertension cases seen by the neuropsychiatrist were potentially mental subjects. They required comforting assurances, but at the same time a clear understanding that untreated they were subject to the dangers of developing brain, heart, and kidney diseases. They should be trained in the habit of quiet living, moderate salt intake, and reduced fluid intake to a degree compatible with renal health. They should learn that drugs were not used for hypertension ordinarily, but were applied for specific complications. Hypertension patients should be educated to a realization that less worry and more optimism were desirable. Food should be desired by the hypertension patient in quantities only sufficient to maintain a minimum of weight compatible with health. They should learn that using teeth for purposes other than digging one's grave, figuratively speaking, in suicidal gormandizing practices at the dining table would surely be rewarded by a reasonable degree of good health, happiness, and longevity.

The Mental Disease Problem.—Dr. George L. Echols, of Milledgeville, Ga., said that mental disease was a staggering problem, economic, social and humanitarian. Mental disease was apparently on the increase. A person requiring hospitalization from a neurosis or psychosis was just as much incapacitated and had a disease just as real as another person with a fractured leg or pneumonia. These conditions were most amenable to treatment in the prepsychotic and early psychotic period, and it was the family physician who saw the patient in this period.

Bacillus Acidophilus; Results of Feeding Milk Culture.—Dr. George C. Mizell, of Atlanta, Ga., stated that relief from chronic intestinal stasis and toxemia of the putrefactive type, even in the presence of intestinal adhesions, had been secured by feeding bacillus acidophilus milk culture in conjunction with a general diet. Chronic ileocolon and colon stasis of undetermined origin, as well as secondary to intestinal adhesions, might be relieved by feeding bacillus acidophilus milk. When results were not so secured, additional measures of a nonirritating character directed to the relief of the constipation and some modification of diet might render the treatment effectual.

Spasm at the Cardia and Cardiospasm.—Dr. Julius Friedenwald and Dr. Theodore H. Morrison, of Baltimore, Md., stated that from their study of 133 cases of spasm of the cardia and cardiospasm, as well as from the cases recorded in the literature, they had come to the following conclusions: It was extremely important to differentiate between the two affections. While the former was purely an acute affection noted in neurotic individuals, the latter was chronic in character associated with more or less organic change about the cardia, with a certain degree of dilatation of the esophagus. A thorough clinical study, with fluoroscopic and esophagoscopic examinations, would usually clear up the diagnosis without difficult. While spasm at the cardia could usually be treated successfully by means of the simple methods originally employed in overcoming functional nervous affections, cardiospasm could only be overcome by means of forcible dilatation. Since spasm at the cardia was purely a functional condition and usually preceded the more serious and organic lesion of cardiospasm, early recognition and eradication of the former would do much prophylactically in diminishing the incidence of cardiospasm.

Cancer of the Stomach.—Dr. John B. Fitts, of Atlanta, Ga., said that early stomach cancer presented no special syndrome. Dyspeptic symptoms in previously well adults should be accounted for. Patients suffering from long continued digestive disturbances should be frequently reexamined. Thorough chemical, microscopical and röntgen examinations gave positive evidence for or against an existing malignancy.

Tropical Sprue.—Dr. Daniel N. Silverman and Dr. Willy Denis, of New Orleans, La., stated that the results of their observations in the case reported did not warrant any general conclusions. They had shown that the enzymes of duodenal contents in a case of sprue were present to a considerable extent during the clinical course of the disease, and that these enzymes greatly increased in strength even up to normal amounts during clinical improvement of the case. These facts would lead them to believe that in tropical sprue the pancreas did not always undergo extensive or permanent damage and that this gland might assume its normal digestive function.

Digestive Hemolysis as a Test of Liver Function.—Dr. A. L. Levin, of New Orleans, La., said that from a study of the forty cases reported by him and a number of cases studied by others, he had come to the following conclusions: 1. Liver pathology could probably be detected early by the test of digestive hemoclasia of Widal. 2. In a study of gallbladder infections, it should be borne in mind that the pathology often began from the liver end, and if this was true, attention should be directed to that organ first. 3. The socalled intestinal toxemias and simple cases of indigestion were probably of hemoclastic origin. 4. Hepatic opotherapy undoubtedly influenced the Widal hemoclasia test. 5. A large proportion of cholecystitis and cholelithiasis cases gave a positive hemoclasia of Widal and the results of treatment, whether medical or surgical, should be checked up by the Widal liver test. 6. Diseases arising from protein hypersensitiveness should be studied by this test. 7. The test was not conclusive, but it invited enough interest for further observation and study. 8. It should be adopted as a routine laboratory test.

Deafness in Congenital Syphilis.—Dr. Albert Keidel and Dr. Jarold E. Kemp, of Baltimore, Md., reported twenty-two cases of deafness due to late congenital syphilis. The incidence of this form of deafness was approximately ten per cent. Males were more susceptible, particularly negro males. The age of onset approximated that of puberty. The onset might be sudden or gradual and was usually accompanied by tinnitus and vertigo. The symptom complex was characteristic. Active manifestations of congenital syphilis other than aural lesions coexisted with or antedated the malady and were often of unusual severity. Of these interstitial keratitis was the most common. The blood Wassermann test was positive in over ninety per cent. of the patients, spinal fluid was invariably negative for abnormalities due to cerebrospinal syphilis. Cranial nerves other than the branches of the eighth were rarely involved. The prognosis was not good, and the results of treatment were poor. Adequate treatment of all patients with congenital syphilis was advocated as a prophylaxis for late aural involvement.

Relation of Gastroenterology to Other Specialties.—Dr. A. W. Galloway, of Asheville, N. C., said that a gastroenterologist had a field sufficiently large of his own and need not depend upon an intimate relation with other specialties. There were many good reasons for group association governed by local conditions. Any group which could thereby render greater service than by individual effort was not to be criticized. He deplored, however, an association or grouping of physicians, which might have a combined fee. Gastroenterologists did that part of general medicine which fell to their inclination. He believed their most important work was in the proper application of diet.

Ileocolon Stasis; Its Clinical Consequences and Treatment.—Dr. Sidney K. Simon, of New Orleans, stated that in the treatment of chronic intestinal stasis, first in importance was the diet, next the carrying into execution of a well directed plan of abdominal exercises, which should be insisted upon as a regular routine, twice a day, and persisted in for several months. Pharmaceutical products should be made to play an insignificant rôle. Surgery in refractory cases of long standing had been enthusiastically advocated by Lane, Moynihan and others in England, and by Bainbridge in this country. He believed that this radical plan of procedure should be limited to the cases in which medical treatment had failed.

Congenital Syphilis.—Dr. Stewart H. Welch, of Birmingham, Ala., said that the present laboratory procedures were inadequate. Further progress apparently depended on more reliable laboratory assistance. Therapeutically, congenital syphilis demanded the same consideration given to acquired syphilis. The practice of intelligent obstetrics was important in the minimizing of irreparable damages, the subsequent treatment, and the possible prevention of congenital syphilis.

Vaccines in the Treatment of the Secondary Infection in Pulmonary Tuberculosis.—Dr. C. H. Cooke, of Asheville, N. C., said that autogenous vaccines should never be used in pulmonary tuberculosis as a routine measure. They were of very limited value and should be administered only in selected cases free from demonstrable foci of infection which had been sufficiently studied to warrant the attempt at specific therapy because of failure of the usual routine conservative measures. They should never be used to the exclusion of these measures, and if reliance was put upon them without regard to more essential matters, a great deal of damage would result. The dose should be carefully calculated and an attempt at a general reaction of serious nature should not be made. Persistence in their use after a fair and honest trial in the individual case without improvement on the patient's part should be sufficient grounds for discontinuance.

Sugar Findings in Normal and Pathological Spinal Fluids.—Dr. A. G. Kelley, of Atlanta, Ga., stated that the sugar content of cerebrospinal fluid was decreased in untreated cases of syphilis of the nervous system, in meningitis due to the meningococcus, the staphylococcus aureus and the pneumococcus, and in moribund cases. As cases of syphilis of the nervous system were treated, the sugar content gradually approached the normal, and on this account repeated estimations of the sugar content of the cerebrospinal fluid in these cases might possibly be of prognostic value. There was sufficient evidence to warrant the opinion that the treponema pallidum when present in the cerebrospinal fluid utilized the sugar normally present in the fluid.

Diagnosis of Abdominal Adhesions.—Dr. C. W. Strickler, of Atlanta, Ga., stated that the majority of these cases were curable if the patients were operated upon by a surgeon who understood the development and rotation of the gut with the abnormalities as described by Huntington, and who made an incision of sufficient length to view his work. He emphasized the fact that the smaller and more or less obscure adhesions gave even more trouble than the large ones. Following surgical procedure the patient should have the care of a competent clinician until health was fully restored. If this could be done in all cases, failures would be conspicuous by their absence, and many of the so-called abdominal invalids would have something worth while done for their relief. The length of time necessary to obtain the desired results depended upon the number of months or years the patient had suffered from the distressing symptoms. In his experience relief had come in some cases within a few weeks, in others of long standing, two years were required for complete restoration to health.

Aplastic Anemia.—Dr. Bryce W. Fontaine, of Memphis, Tenn., said that aplastic anemia, although rare, did occur with sufficient frequency to render difficult its diagnosis from several commoner diseases of the blood and abdominal viscera. No reliance could be placed upon the study of the blood smear alone, for it might resemble one or several of the severe anemias. It was possible to differentiate all the severe anemias—those that were marrow regenerating, those that were nonregenerating, and those that were entirely secondary, as in the cases of cancer of the stomach and cancer of the cecum—by a correlation of all the physical signs, analysis of the gastric contents, quantitative estimation of the bile pigments in the duodenal contents, feces and urine, the bleeding time, the resistance of the red cells to various dilutions of salt solution, the presence of skeined and reticulated cells, when the blood was stained with cresyl blue, the total and differentiated blood count, hemoglobin reading, the color index, the platelet count, x ray study of the stomach and cecum for filling defects, study of the bone marrow obtained by bone puncture, and least important of all, the study of the stained blood smear.

(To be concluded.)

Abstracts from Current Literature

ORTHOPEDIC SURGERY

Open Reduction of Congenital Hip Dislocation.—M. A. Bernstein (*Journal of Bone and Joint Surgery,* July, 1922) says that the difficulty in reducing a congenital dislocation of the hip joint increases with the age of the patient. The chief difficulty in reducing a luxation by the closed method is the inability of passing the head of the femur through the narrow neck of the capsule. This has been recently emphasized by Galloway. When the head is once reduced it can be retained by the usual method. In older individuals the depth of the acetabular cavity and shape of the head of the femur are not the chief considerations for a successful reduction. Shortness of the soft structure, muscles, nerves, and bloodvessels are great obstacles. At the age of fifteen or twenty, the muscles, nerves, and bloodvessels have become normal for that individual, and to overcome shortening of four or five inches is a great task. It is therefore necessary to sacrifice muscular attachments. In performing this operation one should first inject the sacral canal to overcome the distressing pain from nerve stretching. One must also take particular care not to injure the bloodvessels. In the case reported there was no evidence of circulatory disturbance.

Congenital Dislocation of Hip.—E. Laming Evans (*British Journal of Surgery,* July, 1922), from a study of forty-nine cases of congenital hip dislocation, gives the following summary: 1. Concentric reductions without any changes in head and neck are good. 2. Concentric reductions with changes in head and neck vary; some are good, others fair. I have to record one bad result in this class—an ankylosis in external rotation and abduction with coxa vara of 90 degrees. 3. Exentric reductions depend upon the degree of absorption. Three cases show good functional results and two fair. It is still too early to say whether progressive arthritic changes will not vitiate these early satisfactory results. He is not optimistic on this point. 4. Anterior transpositions give good functional results as a rule. 5. Posterior redislocations are indistinguishable from untreated cases. Evans's method of reduction was founded upon Lorenz's technic: gradually forces were diminished and muscles spared, so that his later cases were reduced by a much more gentle and less disruptive process than the earlier ones. Except in a few cases where he used internal rotation after Lange's method of retention, he has employed a short spica reaching from the waist to above the knee. Early locomotion on a high patten has been adopted. In bilateral cases the period of retention in plaster has been shortened as much as possible—from three to six months. In unilateral cases he has kept up retention for much longer than is usually accepted—eighteen months to two years. With few exceptions retention has been maintained in 90 degrees flexion, 70 degrees abduction, and an indifferent rotation. Werndorff's axillary abduction has promoted successful retention in difficult cases where the acetabular roof has been markedly deficient. After removal of the plaster, abduction in walking has been secured by applying an inch and a half patten to the sound side. He attaches great importance to a plaster bed made according to the formula 90, 70, 0, up to the end of the third year after successful retention. In unilateral cases one hip only has been enclosed in the plaster. Exceptional cases have been treated with modifications according to the structure and stability of the joint; but, in general, the above may be taken as routine. He has fractured some necks, but no femoral shafts: has had no nervous or arteriovenous complications. There has been one tragedy—the death of a patient, eight and a half years after reduction, from double pneumonia, without a postmortem examination.

Synovial Membrane Joint Tumors.—F. W. Hartman (*Surgery, Gynecology, and Obstetrics,* February, 1922) states that the occurrence of this tumor in joints, and especially in the knee joint, raises at once the problem of saving the limb and function of the joint. Their development is slow as a rule and ample warning is always given in the form of pain, swelling, and interference with function. They are readily removed, if attacked in the early pedunculated stage, without danger of local recurrence or remote metastases. As to classification, it seems best to place them with the benign tumors of connective tissue origin since the giant cells are of the foreign body type and no mitosis is seen. However, there is a potential malignancy, as demonstrated in the patients of Lejars and Rubens, of Kruger and of Garre. Palliative measures and incomplete excision are contraindicated and are perhaps responsible for the malignant characteristics developed in these cases. These neoplasms should not be termed sarcoma, at least until evidences of malignancy are seen either clinically or pathologically. Since any one of the characteristic cells, namely xanthoma or foam cells, pigmented cells and giant cells, may be absent from an otherwise typical case, the writer prefers the name used by Woodhead, namely, myeloid tumor.

Treatment of Chronic Synovitis of the Knee Joint.—G. Gelston Atkins (*British Medical Journal,* June 17, 1922) finds that a strain of the internal lateral ligament of the knee joint causing an effusion into the joint is a common injury. As a result of such an injury the vastus internus muscle is thrown out of action, causing it to lose its tone and waste rapidly. By treatment the effusion is got rid of, but owing to the weakened condition of the vastus internus muscle, any small twist of the joint again strains the knee with the result that more fluid accumulates and the vastus internus is weakened more, thus establishing a vicious circle. This condition may be effectively treated by reeducation of the vastus internus muscle by causing the patient to keep his leg perfectly straight and to practice daily the bracing up of the vastus internus; with severe wasting, an artificial stimulus, like the Bristow coil, is advised. The thigh muscles are massaged and subjected to contrast baths of hot and cold water. The effusion is got rid of by increasing the blood supply around the joint. The patient is allowed light exercise and is instructed not to walk over uneven ground. A tight bandage over wool may be applied to the joint at night. In some cases the fluid must be aspirated.

Treatment of Traumatic Synovitis.—C. A. McWilliams (*Annals of Surgery,* December, 1922) asserts that repeated aspirations combined with active (never passive) motions, and walking without splints afford the best method of treatment of acute and chronic, traumatic, joint synovitis, provided there be no joint mouse nor dislocated meniscus present. Aspiration should be immediately performed in all types of traumatic joint effusions as it relieves pain immediately, renders a correct diagnosis more certain, prevents stretching of the ligaments with their consequent weakening, and avoids subsequent muscular atrophy. Such treatment makes unnecessary all other subsequent physiotherapeutic measures, hence its simplicity makes it applicable to all classes of patients. Such a method of treatment produces a more perfect cure in half the time that is required by the old immobilization method. To leave fluid in a knee, the result of trauma, is just as irrational as to leave fluid in a chest unaspirated. Aspiration of a knee is a simpler procedure and less dangerous than aspiration of a chest, and can safely be performed in a doctor's office or a dispensary, and the patient thereafter can be immediately sent home walking. The effects of physiotherapeutical measures have been overestimated, being used empirically and without foundation. They are makeshifts to excuse procrastination in not applying a radical, curative procedure such as aspiration.

Pseudocoxalgia.—H. Platt (*British Journal of Surgery,* January, 1922) gives the following summary of pseudocoxalgia: 1. Pseudocoxalgia or osteochondritis deformans juvenilis coxæ is a definite entity representing the reaction of the metaphyseal region of the upper end of the femur to the stimulus of an infective agent of attenuated virulence. 2. The condition is comparable with the arthritis deformans juvenilis coxæ which is seen solely in adolescents, and which represents at this age period the reaction of the hip joint to an infective agent of a similar type. 3. The whole cycle of radiographic changes is peculiar to pseudocoxalgia alone. They precede and outlast the clinical phenomena. The final picture is dominated by the deformation of the head of the femur, which is enlarged and flattened. The acetabulum in its final form can no longer contain the whole of the expanded head. 4. Deformation of the head of the femur with flattening and expansion is seen also in conditions distinct from pseudocoxalgia during childhood. There is no evidence to show that in these conditions the typical structural osseous changes of pseudocoxalgia have preceded the stage of flattening. At certain stages the clinical and radiographic pictures of the two groups of affections may show considerable resemblance. This applies particularly to cases of primary tuberculous osteomyelitis of the femoral neck. 5. In the conditions known as tarsal scaphoiditis (Köhler's disease), and apophysitis of the tibial tubercle (Osgood-Schlatter disease), bony changes parallel to those in pseudocoxalgia are found. 6. Conservative treatment directed towards the elimination of weight bearing has no proved influence on the train of morbid changes, but its application is indicated during the stage of prominent symptoms. Operative treatment directed towards the removal of the dominant lesion has no present place in the therapeutics of this disease.

Treatment of Osteomyelitis.—Max Thorek (*Annals of Surgery,* January, 1923) in describing the use of aluminum potassium nitrate in the treatment of suppurative conditions particularly osteomyelitis, states that the treatment is not in any degree a substitute for rational surgery, but must be considered as a preoperative treatment in badly infected cases, enabling the surgeon to later work under more favorable conditions. As a postoperative treatment in infected cases irrespective of whether the case was previously or subsequently infected. As a procedure in those cases that have failed to respond to previous surgical measures and those patients who persistently decline operation. Removal of sequestræ is in all cases advisable. The aluminum potassium nitrate compound is not an antiseptic, but, on the other hand, is a definite accelerator of bacterial growth, tending by rapid propagation to lower the vitality of the infecting organisms thereby assisting the normal resisting powers of the body to eliminate the invading organism. Unlike most antiseptics, the aluminum potassium nitrate compound does not attack normal tissues and does not interfere with granulation or the osteogenetic efforts of nature. Pain, which in most cases is the result of infiltration and consequent tension, is very quickly relieved, due to prompt autolysis and liquefaction relieving tension by absorptive elimination through sinus or systemic absorption. Over seventy-five per cent. of our cases become ambulatory and are able to pursue their vocations, coming to the clinic for dressings in contrast to the radical surgical procedures of the past, thus eliminating long hospitalization and later invalidism with its attendant expense. The method is relatively simple, may be used within wide limits, and employs a nontoxic medicament.

Osteitis Fibrosa. — Young and Cooperman (*Annals of Surgery,* February, 1922) present a study of Von Recklinghausen's disease with a report of a case presenting multiple cysts and giantcell tumors and conclude that osteitis fibrosa, under which may be included benign bone cysts, giantcell sarcoma of the epulis type, hemorrhagic osteomyelitis and the generalized form (Von Recklinghausen's disease) is a distinct pathological entity characterized by a fibrous metaplasis of bone. Two types of the disease are recognized, a local and a general type. Local osteitis fibrosa and benign bone cysts are dependent upon trauma in a great majority of instances. The general form is dependent upon grave nutritional disturbances. Endocrinal glandular dysfunction, faulty calcium metabolism and chronic infection of a low grade seem to be of etiologic significance. Cysts, osteitis fibrosa cystica and giant cells may occur in the same bone. The giantcell contents is not prognostic of malignancy. Diagnosis of osteitis fibrosa is based upon the long duration of this process with very vague symptomatology, the frequency of spontaneous fractures and upon x ray examination. Very often microscopic examination of pathological sections is necessary to clear up the diagnosis. The local form of the disease is benefited by curettage and bone transplant. The type showing multiple lesions must be given constitutional treatment directed toward the underlying constitutional disturbance. If the lesions are accessible, curettage and bone transplant may be employed.

A Case of Avulsion of the Tuber Calcanei.—Anton Mülleder (*Wiener klinische Wochenschrift,* July 27, 1922) reports a rare case of avulsion of the tuber calcanei in a man, sixty-one years old, as a result of a fall from a scaffold. The entire foot was swollen and suffused, especially around the heel. About three finger breadths above the edge of the os calcis, a sharp spicule of bone was felt almost piercing the skin. The röntgenogram revealed an avulsion fracture of the tuberosity of the os calcis and dislocation of the proximal fragment upward, with a constant contraction of the tendo Achilles. At operation, a hematoma cavity as large as a child's fist was found and the broken off piece of bone was drawn upward and medially and turned about ninety degrees. On extending the foot, the fragment could be replaced and it was sutured in place with silk ligatures, including the insertion of the plantar fascia, the periosteum and the insertion of the tendo Achillis. A cast was applied to the foot in extension. Recovery followed but the patient was hindered considerably from walking, especially for any length of time. This is the usual result. The question whether such fractures result from direct or indirect injury is undecided, although the author believes that in this case the cause of the fracture was direct injury, aided by the arrangement of the bone trabeculæ and the abnormal tension on the musculature. Most surgeons favor a conservative therapy, but if this fails surgery is indicated. In this case conservative therapy was contraindicated because of the torsion of the fragment and the threatened perforation of the skin. The author favors radical treatment together with a simultaneous tenotomy.

Rheumatoid Arthritis and Its Practical Treatment.—Leonard Dobson (*West London Medical Journal,* October, 1922) thus summarizes his paper: In all cases of arthritis make a thorough examination to see whether one has to deal with a direct specific infection, such as syphilis, tubercle, gonorrhea, or the like, including an examination of the blood, feces and urine. Do not, because you obtain a positive Wassermann, at once come to the conclusion that you have only syphilis to deal with. If there is much pain and inflammation it is possible that there may be another cause. Failing these make a thorough search for some focus of sepsis either in the mouth, nasopharynx, alimentary canal, bladder or uterus and its appendages, or other parts of the body. Do not if you see pus oozing from the margins of the gums, at once decide that this is the sole cause of the trouble and order all the teeth to be removed. It may not be of any service, and few artificial dentures are a really satisfactory substitute for the natural teeth. At the same time all really diseased stumps should be extracted. If the urine or feces give positive evidence of the presence of microorganisms which are likely to cause trouble, let an autogenous vaccine be prepared and administered, but do not rely entirely on this. Similarly, if the urine shows the presence of products of intestinal putrefaction, such as indican, indol and skatol, subject the patient to a thorough course of intestinal lavage daily for a period of three weeks, then every other day for a similar period, and finally once a week. At the same time give a morning dose of half an ounce of paraffin and an aloin and belladonna pill in the evening. Place a blister two inches square over the seventh and eighth cervical and tenth to twelfth dorsal vertebræ, and keep these open by dressing daily with savin ointment. Treat all acutely inflamed joints by means of rest, heat baths, suitable splints, and bandaging. Chronic swelling is best treated with hot air baths, Scott's dressing, occasional blisters, Bier's congestive treatment, and the other means already described. Finally, when the disease seems to have come to an end, encourage movement by exercises, massage and manipulations.

Paget's Disease.—P. Lewin (*Journal of Bone and Joint Surgery,* January, 1922) includes a report of three cases in his study and gives the following treatment. Preventive treatment is impossible because of the difficulty of diagnosis before deformity has set in. Curative treatment at present is impossible. Corrective treatment may be inadvisable because of the age of the patient and the probability of failure. Funk hopes to offer something of value in the treatment from the standard of calcium metabolism. Arsenic has been given internally in all its forms, and the results are questionable. There have been recommended by various authors prepared bone marrow, codliver oil, calcium lactate, thymus gland. One writer recommended giving proteins, but no carbohydrate. For the present it seems that the best hope is offered by the administration of phosphorus internally; for example, in the phosphorus pill of a hundredth of a grain three times a day, continued over a long period. Goldthwait, Painter, and Osgood reported a case in which the patient suffered a fracture of the affected thigh from a severe trauma. The broken bone healed with apparently normal rapidity and firmness. This encouraged them to recommend osteotomies for the correction of marked but slowly developing deformities, especially of the lower limbs.

Fracture of the Spine.—W. J. Mixter (*Journal of Bone and Joint Surgery,* January, 1923) says that many fracture crushes of the spine, without cord involvement, are unrecognized. A great many physicians think that if a man can walk he has not fractured his spine, and treat him for sprains and contusions of the soft parts. The majority of fracture crushes of the spine receive no adequate treatment. They are allowed up after periods of from one to eight weeks in bed without any support and gradually break down and deform. It is highly essential, no matter how long patient has been in bed, that he have adequate support in order to restore, partially at least, the normal function of the spine, while at the same time preventing the occurrence of deformity until the return of full function is permissible. We have found that the spinous processes of the fractured vertebræ will be tender until the healing of the vertebra has taken place and all strain has been taken from it. It is very easy to fracture a vertebra if weight is applied to the top of a slightly flexed spine. All cases of fractured spine should be corrected and put in the best position and then held in that position until Nature has repaired it. This should be at least six months. It is unnecessary to do any operation on the spine for internal fixation. Every case of suspected fracture of the spine should have a thorough x ray examination, and that means plates taken anteroposteriorly and laterally.

Bone Grafting as an Aid in Treatment of Tuberculous Spinous Caries.—Henry W. M. Gray (*British Medical Journal*, July 15, 1922) believes that bridging the tips of the spinous processes of the vertebræ, as is done in the Albee operation, does not give sufficient fixation, as a certain amount of give in the spinous processes and grafts is necessary, especially in the dorsal region of the spine, which is the part of the spine most often affected by the disease. The fixation is uncertain because the graft is inserted at quite a distance from the articular processes and the intervertebral discs, where motion takes place and the unsatisfactory results often seen are due to the inadequate fixation, especially in the younger children. In the more recent method of Hibbs, the fixation is better but the operation is complicated and severe and is usually not as successful as the author's operation. This consists of placing tibial transplants into grooves made in the spine. The periosteum of the spinous processes and laminæ is reflected, the exposed bone is roughened with a chisel and the grafts are placed with the periosteum outermost. The edges of the aponeuroses are approximated across the midline with catgut sutures and the wound is closed without drainage.

Osteitis Deformans.—Sydney M. Cole (*Journal of Bone and Joint Surgery*, October, 1922), from a study of Paget's disease, concludes as follows: There is osteoporosis with disappearance of bone by lacunar absorption and chemical (vital fluid?) dissolution, accompanied by new formation of bone. In the author's case the new formation is not so marked as in those reported by others. The active process seems to have been completed. There is evidence of breaking down of bone—he would say bending of trabeculæ crushing down on neighboring cancelli, obliterating some canals and assisting in the formation of others. There is marked vascular degeneration with varicose vessels, thrombosis, congestion, leakage with edema and minute hemorrhages. The surrounding tissues are modified to a certain extent as evidenced by changes in vessels, nerves, muscles, and tendons. It is suggested that this is due to the bone absorption in their neighborhood throwing them in contact with unaccustomed (unusual) neighboring material. In the case of muscle attachments the distortion and microscopical changes are especially marked. The bone itself shows reversion to a fibrous type in places; there is a metaplasia to myxomatous tissue and the marrow is myxomatous, fibrous or cellular, the bone cells taking part in the process. There is what appears as a reversion of marrow in some bones to the embryonal type—containing small and large round cells, megalokaryocytes and normoblasts—possibly compensatory. The bone cell multiplication is an essential part of the disease. The pathological changes vary in the different bones and in various parts of the same bone. This will be noted, too, in the appended pathological reports of various cases by different workers. There is evidence of analogous conditions to bone in the organs and tissues (see kidney, spleen, muscle), and nerves. This is best noted in the tendency to overgrowth cell multiplication. The circulation has been erratic for years with intermittent compensation and the reverse, the bones, organs, and soft parts being correspondingly affected. The changes involved correspond to what one finds in chronic inflammation or in resolution of acute inflammation where repair is the most important factor. His impression is that there is a primary bloodvessel pathology like one sees in syphilis, hereditary or acquired, with accompanying bone changes, such as one finds on a small scale in chronic passive congestion or infections of a chronic character. It is not at all improbable that malaria, typhoid, influenza, erysipelas, or parasitic germs could produce such vascular lesions, accompanied by local and general osteitis deformans.

Treatment of Fractures.—T. S. Mebane (*Military Surgeon*, August, 1922) concludes that all fractures should be splinted before transportation. For this purpose, except under war conditions, coaptation splints, Thomas or Keller leg splint, and Cabot posterior wire splint, are the splints usually required. Many compound fractures can be converted into simple fractures by prompt application of iodine and a sterile dressing. Where considerable laceration of the soft parts has occurred, débridement with primary or secondary closure should be practised. Infected compound fracture should be treated by Carrel-Dakin technic with suspension in Balkan frame and traction to preserve alignment. Simple fractures and compound fractures present differences which require that they be handled differently. Convalescence in fracture cases can be shortened and function conserved by employment of physiotherapeutic measures, early use of the part, and employment of braces and supports until callus becomes firm.

New Plaster Shell in Pott's Disease.—R. Plato Schwartz (*Journal of Bone and Joint Surgery*, October, 1922) summarizes as follows: 1. The defects of the old shell have been revealed and it has been made a practical instrument through which the fundamental principles of therapy may be applied in the treatment of Pott's disease. 2. X ray controls are necessary to prove its efficiency. 3. The fulcrum should not be placed opposite the apex of the kyphos except in the region of the seventh dorsal vertebra. 4. In lesions above the seventh dorsal vertebra the fulcrum should be made below the apex of the kyphos, quarter of an inch for each vertebra above this level. 5. In lesions below the eighth dorsal the fulcrum should be made above the apex of the kyphos, approximately quarter of an inch for each vertebra below this level. 6.The new shell with an adjustable fulcrum has thus far, in a limited number of cases, overcome the defects of the old one. It is much more comfortable for the patient, easier to handle, and much less expensive; besides being fully practical for treatment in the home and out patient department.

Ligation for Aneurysm.—C. Balance (*British Journal of Surgery*, January, 1922) concludes that cases about to be submitted to operation should not be previously treated by the method of Valsalva; that there is a group of cases of aneurysm of the innominate artery (aneurysm of the bifurcation) suitable for proximal ligature. Distal ligature causes the aneurysm to become a diverticulum of the aorta, and so increases the pressure within it, and should not be done when proximal ligature is possible. The presence of the aneurysm necessitates removal of a part of the sternum in order to gain a free and clear exposure of the vessel below the aneurysm.

Tendon Transplantation.—Robert Ollerenshaw (*British Medical Journal,* July 15, 1922) states that the transference of muscle power may be used, 1, to restore loss of motion from injury of the peripheral nerve, as in poliomyelitis; 2, to redistribute the power acting about a joint; and 3, to diminish the unopposed action of nonparalyzed muscles which cause a deformity. Tendon transplantation should not be undertaken until the full extent of the amount of paralysis is positively determined. Constant splinting and physiotherapy must be given a sufficient trial. The transplantation does not produce an increase of muscular power but the power is more usefully distributed. The operation is chiefly indicated when the paralysis is limited to a group of muscles and where other muscles (not antagonistic) are available for transplantation. Around the ankle, only a redistribution of power can be expected. The simple flexion and extension movements of the ankle should be retained and the subastragaloid joints should be fixed by arthrodesis. The technic includes the correction of all deformities. Secondary changes in the bones and joints may require wrenching and fixation in the overcorrected position for a time. The skin in the field of operation is carefully prepared for operation for three days and the strictest asepsis must be maintained. The best results are obtained with the transplantation of the entire tendon (not slips of tendons) which is fixed as close to the insertion of the paralyzed tendon as possible, best by suture. If the transplant is too short, the paralyzed tendon is buttonholed and the transplant is passed through and firmly sutured to it. The transplanted tendon should run in as straight a line as possible. The limb is then fixed so as to secure as much relaxation of the transplanted tendon as possible without producing strain on the sutures. The aftertreatment consists of complete fixation for six to eight weeks, at which time removable supports are provided. The reeducation of the muscles is aided by physiotherapy.

Injection of Oxygen in Joints for Diagnosis.—S. Kleinberg (*American Journal of Surgery,* September, 1921) says that when he first began his work with the injection of oxygen into joints he was hopeful that this method would enable him to outline loose or injured semilunar cartilages. In this he had been unsuccessful, although on one occasion shadows were obtained which appeared logically to outline these structures. However, in reviewing his experiences he believed that there was no doubt that the injection of oxygen into joints for röntgenography had many advantages and was a great aid in diagnosis. Primarily it accentuates the contrast between the soft parts and bones, and brings into relief soft structures that are not discernible in the ordinary röntgenograms. It is very useful in demonstrating loose bodies in joints, and it is invaluable in locating them. It is helpful also in showing the presence and extent of hypertrophied synovial tissue.

Treatment of Scoliosis.—A. M. Forbes (*Journal of Bone and Joint Surgery,* July, 1922) gives the following summary as the result of his surgical treatment of scoliosis. Although operative procedures for scoliosis cannot be considered to have stood the test of time, they have been sufficiently encouraging to permit us to continue their employment. We have never operated for cosmetic effects and we have purposely operated only in a limited number of patients under the conditions already mentioned. We hope that the day will come when the field of usefulness of operative procedures may be extended, but we would hesitate to recommend their general use, because, as we have already stated, the operation is a severe one. It should not be carried out except after deep thought and consideration, and then only by those who are accustomed to operate on the spine. Perhaps at a later date its field of usefulness will be broadened, but until we have been able to prove the enduring character of the ankylosis and the general benefit to the patient we have no right to employ it except in desperate cases.

Cervical Rib.—S. W. Boorstein (*Journal of Bone and Joint Surgery,* October, 1922), from a study of six cases which he reports, concludes that many cases coming to the orthopedic surgeon with shoulder trouble may be due to cervical rib. Cases presenting the following symptoms: pain, especially on motion, cyanosis, and atrophy of the limb, and no limitation of motion, should make one suspicious of a cervical rib. The fullness of the supraclavicular fossa, besides the x ray, should help in the diagnosis. The removal of the rib should be practised by the orthopedic surgeon for the same reason that he removes the transverse process of last lumbar. Where symptoms have existed over a long period, and especially where paralysis and atrophy form part of the picture, removal of the rib will stop the progressive increase of the symptoms, but may not result in the entire recovery of what has already been lost. This indicates the necessity for early diagnosis, and the desirability of good stereoradiographs of the neck in every case of persisting pain or lameness of obscure origin. In all cases of shoulder trouble, x ray of cervical spine should be taken, since, if the cervical rib may not be the sole cause, it may be a contributory cause by interference with the circulation and nerve supply.

Theories and Theorizers Connected with the Development of the Laws of Heredity*

By J. ARTHUR BUCHANAN, M.D.,
Rochester, Minnesota,
Fellow in Medicine, The Mayo Foundation.

As the problems of heredity have been solved in conjunction with the studies of cellular life, the development of the theory of heredity may be divided into two quite distinct periods: 1, the precellular period (? B. C. to 1838 A. D.), and, 2, the cellular period (1838 to the present era).

THE PRECELLULAR PERIOD.

The precellular theory of heredity dates far back in the history of man, and as the theories of the early periods were largely speculative, those on heredity naturally fell into the same category. The speculations, however, often harmonize quite well with our present interpretations of definite facts. This fact is particularly exemplified by the works of Empedocles of Agrigentum (495-435 B. C.), who said, "Living beings are derived from the growing together of incomplete structures and separate members whereby only intrinsically congruous combinations are capable of existing and of being propagated." The diseed origin of man had been expressed more than a thousand years previously by Moses, who, in depicting the origin of the universe, records the first punishment by these words, "And I will put enmity between thee and the woman, and between thy seed and her seed." It seems remarkable that it took so many years before the seeds were discovered as concrete entities.

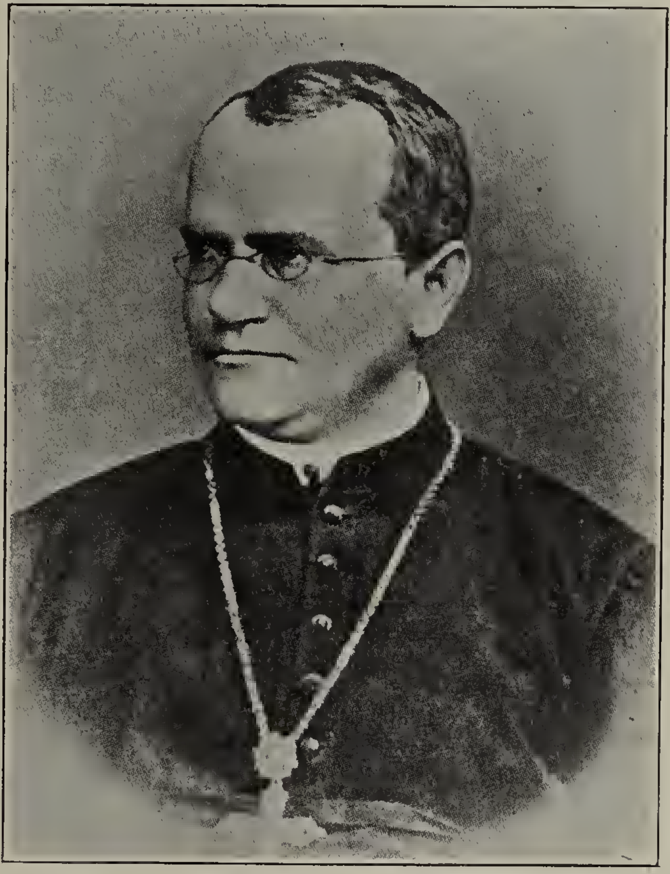

Fig. 1. Gregor Mendel as Prälat.

One is led to suspect that among the early thinkers there was current a belief that animal life developed from decomposing matter, since Pythagoras of Samos denied such a theory in his writings, and asserted the necessary existence of an embryo.

The genetic state of knowledge in the fourth century is well illustrated in a statement by Aristotle (384-322 B. C.), concerning the advancement of learning, "I found no basis prepared, no models to copy. . . . Mine is the first step, and, therefore, a small one, though worked out with much thought and hard labor." Aristotle was the first to conceive of a genetic series, and his conception of a single chain of evolution from polyps to man was never fully replaced until the beginning of this century. He perceived the forces of prepotency, and of atavism or reversion. Of prepotency, he said, "Children resemble their parents not only in congenital characters, but in those acquired later in life. For cases are known where parents have been marked by scars, and children have shown traces of these scars at the same points. A case is reported from Chalcedon in which a father had been branded with a letter, and the same letter somewhat blurred and not sharply defined appeared upon the arm of his child." This idea marks the beginning of the prolonged argument concerning the inheritance of mutilations or acquired characters. Aristotle, however, had evidently imag-

ined the elements of the theory later advanced and known as pangenesis, since he expressed disbelief in the possibility of such a mechanism. He did not believe in the inheritance of normal functional modifications.

Theory of telegony.—The fanciful ideas of early observers in heredity are expressed in the theory of telegony, or impregnation. This was formulated about 1530 as a result of observations made by Fouilloux, who believed that a bitch always gave birth to pups that bore characters of the first dog with which she had been crossed. The same phenomenon has been reported in man, but such observations have not been authenticated. Darwin and Spencer both reported instances of what they considered telegony. The theoretical explanation of the occurrence was based on the belief that the first male made a profound impression of a nervous nature on the unformed or forming cells of the ovary, so that all subsequent offspring were affected. The theory of impregnation of an ovum while still in the ovary was advanced; while in the uterus the first fetus was also believed to produce a lasting influence on all later formed ova. The theory of telegony still has its exponents, and as late as 1921 was of sufficient interest to attract the attention of the French Academy. The review at that time, however, was more patriotic and nationalistic than scientific, as the theory has been demonstrated by many investigators to be entirely false.

The theory of epigenesis.—The first really distinct theory of heredity was that of epigenesis, advanced by Malpighi and Leeuwenhoek in the seventeenth century. Malpighi's observations were made on the unincubated egg in the heat of the Italian summer, and the eggs may have reached a fairly advanced stage of development before they were opened. Malpighi wrote, "Frequently I opened the sac with the point of a needle, so that the animals contained within might be brought to the light, nevertheless to no purpose; for the individuals were so jellylike and so very small that they were lacerated by a light stroke. Therefore, it is right to confess that the beginnings of the chick preexist in the egg; and have reached a higher development in no other way than in the eggs of plants." He believed that the elements of the germ cells were gathered from all parts of the body, and he adumbrated Darwin's theory of pangenesis. Malpighi clearly perceived the struggle for existence and the survival of the fittest.

The theory of epigenesis was correlated by Swammerdam, and published by Boerhaave in *Biblia Naturae,* in 1737. Swammerdam had observed that the parts of butterflies and other insects are discernible at a very early stage. While observing caterpillars just before pupation, he saw in outline the organs of a future stage, and naturally concluded that development consists of an expansion of already formed parts.

The theory of epigenesis became further complicated about 1677 when Leeuwenhoek discovered the fertilizing filaments of the human ovum. Priority in this discovery has also been claimed by Hamm and by Hartsoeker. Leeuwenhoek, Hartsoeker, and others looked on the egg simply as a nidus within which the sperm developed, and they asserted that the future animal existed in miniature in the sperm (Fig. 3). These controversies gave rise to the schools of the spermatists, who believed the sperm to be the animal germ, and of the ovists, who contended that rôle for the ovum.

Fig. 2.—August Weismann, 1834-1914.

The theory of preformation or encasement.—These speculations led to another aspect of epigenesis. Swammerdam, Leibnitz, and Bonnet thought that if the animal germ existed preformed, many generations must be encased within one germ. This gave rise to the fanciful idea of encasement or emboitement (Fig. 3), which was so greatly elaborated by Bonnet, and by Leibnitz who applied it to the development of the soul. Even Swammerdam conceived of the germs of all forthcoming generations as having been located in the common mother Eve, closely incased one within the other.

The controversies concerning the relative merits and demerits of the ovum attracted the attention of Harvey, who expressed, in his dissertation, *On generation,* in 1651, a quaint conception of the function of the ovum. He said, "The egg is the midpassage or transition stage between parents and offspring, between those who are or were, and those who are about to be; it is the hinge or pivot upon which the whole generation of the bird revolves. The egg is the terminus from which all fowls, male and female, have sprung, and to which all their lives tend. It is the result which Nature has proposed to herself in their being, and thus it comes that individuals in procreating their like for the sake of their species endure forever. The egg, I say, is a period or portion of this eternity.

The theory of preformation and encasement met its first bitter opponent in Wolf, in 1759, in his *Theoria Generationis.* He contended that the organs of animals made their appearance gradually, and that he could actually follow their successive stages of formation. He assumed a total lack of organization in the beginning, and was obliged to make development miraculous through the action on the egg of a hyperphysical agent or *vis essentialis corporis.*

The theory of transformism.—The theory of transformism, advanced by de Maupertius (1698-1759), was based on the idea that all material particles of living matter are in some degree invested with physical properties of the higher organism. This idea was later accepted by Haeckel, and forms the basis of his monistic system of philosophy. With regard to the theory of heredity, de Maupertius said, "The elementary particles which form the embryo are each drawn from the corresponding structure in the parent, and conserve a sort of recollection of their previous form, so that in the offspring they will reflect and reproduce a resemblance to the parents. If some of the particles happen to be missing, an imperfect being is formed; . . . if the elements of the different species are united, a hybrid is produced; . . . in some cases a child resembles one of his ancestors even more than its parents; in this case we may suppose that the material particles conserve more strongly the habits they possessed in the ancestral form." This idea permeates the theory of Weismann, which is the fundamental basis of the modern chromosome theory of heredity.

Environment.—The relation of environment to the mutability of species was first generalized by Buffon (1707-1788). In his *Histoire Naturelle,* he said, "In animals, species are separated by a gap which Nature cannot bridge over . . . we see him, the creator, dictating his simple but beautiful laws and impressing upon each species its immutable characters." In 1761 he said, "How many species, being perfected or degenerated by the great changes in land and sea, by the favors or disfavors of Nature, by food, by the prolonged influence of climate, contrary or favorable, are no longer what they formerly were." Later, he said, "One is surprised at the rapidity with which species vary, and the facility with which they lose their primitive characteristics in assuming new forms." In this contradictory manner a field was opened which has always been the arena for debate concerning the influence of environment on hereditary characteristics.

PHILOSOPHICAL TREND.

An excellent illustration of the philosophical trend of investigators in the eighteenth century is contained in the writings of Diderot (1713-1784), in honor of whom the school of philosophy, Langres, France, is named. In discussing the origin of man, he said, "Even if Revelation teaches us that species left the hand of the creator as they now are, the philosopher who gives himself up to conjecture comes to the conclusion that life has always had its elements scattered in the mass of inorganic matter; that it finally came about that these elements united; that the embryo formed of this union has passed through an infinitude of organization and development; that it has acquired in succession, movement, sensation, ideas, thought, reflection, conscience, emotions, signs, gestures, articulation, language, laws, and finally the sciences and arts; that millions of years have elapsed during each of these phases of development, and that there are still new developments to be taken which are as yet unknown to us."

Experimental era.—The experimental period in the study of heredity commenced with Kölreuter (1732-1806), who was the pioneer student of hybrids. He was the first to carry out a series of systematic experiments on plant hybridization, in 1760 to 1766. These experiments not only established with certainty for the first time the fact that the seeds of plants are produced by sexual processes comparable with those known to occur in animals, but also led to a knowledge of the general behavior of hybrid plants, which are scarcely bettered until Mendel made his observations. Kölreuter found that the hybrid offspring of two different plants generally looks as much like the plant which yields the pollen as like that on which the actual hybrid seed is borne. He found that it makes little or no difference in the appearance of the hybrid which of the parental species is the pollen parent (male) and which the seed parent (female); that is, in plants, the result of reciprocal crosses is usually identical. Thus, for the first time, it was definitely shown that the pollen grain plays just as important a part in determining the characters of the offspring as does the ovule which the pollen grain fertilizes. This marked the end of the schools of spermatists and ovists. Kölreuter had no means of discovering that the contents of a single pollen grain unite with the contents of a single ovule in fertilization. He believed that the act of fertilization consisted in the intimate mingling of two fluids, the one contained in the pollen grain and the other secreted by the stigma of the plant. The mingled fluids, he supposed, next passed down the style into the ovary of the plant and, arriving at the unripe ovules, initiated those processes which led to the formation of seeds.

Kölreuter was not aware of the existence of any natural wild hybrid plants. He produced the first artificially bred hybrid in 1760 by applying the pollen of Nicotiana poniculata to the stigma of Nicotiana rustica. The stamens and pollen grains of the hybrid were so poor as often to reach the point of sterility. He backcrossed hybrid with parent until it was impossible to distinguish their respective origins.

While Kölreuter was carrying out his experiments, Lamarck, a philosopher of the French school, was introducing a phase of heredity which was then, as now, the subject of many debates. Lamarck (1744-1829), in spite of being physically incapacitated by blindness, added much to biological knowledge and is especially noted for his views on acquired characters and on variation. His theory of acquired characters is stated in his second law, which reads, "All that has been acquired or altered in the organization of individuals during their life is preserved by generation and transmitted to new individuals which proceed from those which have undergone these changes. All that Nature has caused individuals to acquire or lose by the influence of environment to which they have been long exposed, and consequently by the influence of the predominant employment of a certain organ, or by that of continued lack of use of some parts. . . . All this Nature conserves by generation to the new individuals which arise, provided that these acquired variations are common to both sexes, or to those which have produced these new individuals."

By experimentation Lamarck brought out the results which follow free intercrossing, showing that according to his theory, the effects of environment would be neutralized in the union of individuals which have been subject to different environments, whereas the crossing of individuals subjected to the same environment would hasten to perpetuate the transmission of similar effects. To this principle he refers the fact that the accidental changes induced by the habits of men are not perpetuated, since they do not occur in both parents, whereas the formation of distinct races in widely different parts of the world is due to the uniformity of their environment.

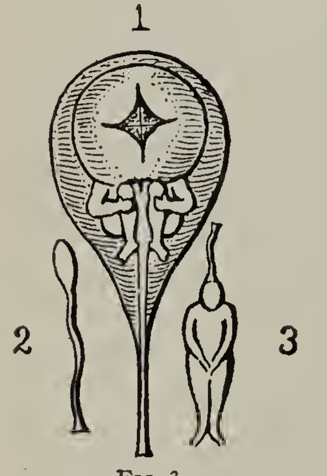

Fig 3.

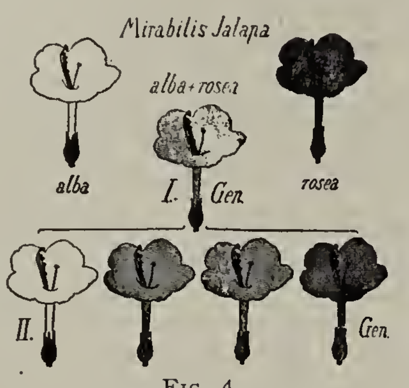

Fig. 4.

Fig. 3.—1, Spermatozoide idea after Hartsoeker. 2, Spermatozoide in envelope stage. 3, Spermatozoide freed from its envelope.

Fig. 4.—A diagram to show inheritance of flower color in crosses of Mirabilis, the "four-o'clock." *Alba*, white parent; *rosea*, red parent; *alba* + *rosea*, the unfixable F_1 heterozygote, of intermediate color, pink. I. Gen. = F_1. II. Gen. = F_2. (After Correns.)

Lamarck will always be remembered for his precipitation of the prolonged discussion concerning variations. He said, "Variations are produced by the use and disuse of organs, by response to external stimuli, and by the direct inheritance of these acquired characters."

It was Lamarck who launched the doctrine of organic evolution, but Darwin connected it with natural selection and, hence, receives all the credit. The basic principle of Lamarck's work is the inheritance of acquired characteristics, and, although this point has been and is still hotly contested, he remains one of the greatest philosophical biologists.

As the tide turned completely away from speculation to experimentation in the study of heredity, Cuvier (1769-1832) came into the breach with a theory of spontaneous generation, the fixity of species, and the preformation of the embryo.

CELLULAR PERIOD (1838 TO PRESENT ERA).

The foremost biological event of the early nineteenth century was the discovery, by Schleidin and Schwann, of the cell in plants and animals. This changed the whole basis of biological philosophy. It is to be remembered, however, that the work of Purkinje, Valentine, John Müller, and Henle had paved the way for this discovery.

The recognition of the cell was soon linked with progress in heredity when von Kölliker (1817-1905), the master zoologist, demonstrated that spermatozoa had their origin in the testicular cells. LaValette St. George (1878) showed that the spermatozoon contains not only a nucleus, as Kölliker believed, but also cytoplasm. Geganbaur (1854) demonstrated that in vertebrate animals the eggs are in reality single cells, regardless of size and condition. In 1875 Hertwig established the all important fact, that fertilization of the egg was accomplished by its union with but a single spermatozoon. Kölliker, although ignorant of Mendel's work, rejected the theory of natural selection in favor of saltatory or spontaneous variations, as he regarded the cell nucleus as the transmitter of hereditary characters. The latter idea bore fruit in the hands of Weismann.

The experimental investigation of heredity on a broad scale was first undertaken by Sir Francis Galton (1871-1897). The theory of pangenesis had been launched by Darwin, and in order to disprove it Galton transfused rabbits with blood from other rabbits, but found that it did not have any effect on the offspring. His observations are now known to mean little, as he did not know the length of life of transfused blood corpuscles (Ashby), nor did he carry the experiments into the second generation. His studies on transfused blood in rabbits, of tricolored spots, of stature, and certain other characters in human families, led him to reject the Lamarckian theory of the inheritance of acquired characters as well as the Darwinian theory of pangenesis. In his book, *Natural Inheritance* (1899), he proceeds to the law of filial regression, by statistical induction, a method introduced into biology in 1845 by the Belgian astronomer, Quetelet. According to this law the offspring of parents unusual in height, talent, and so forth regress to the average of the stock. Galton also formulated the law of ancestral inheritance by virtue of which each parent contributes one fourth of the total inheritance; each of the four grandparents one sixteenth, and each of the eight great grandparents one one hundred and twenty-eighth. The latter theorism has been confirmed, with slight mathematical changes, by the biometrical methods of Pearson.

Galton introduced the doctrine of eugenics (a term of his coinage), founded the Eugenics Laboratory in London (1904), and with Pearson and Weldon founded *Biometrika,* a journal for the study of biological problems by advanced statistical methods.

The statistical work begun by Galton is still going on under the direction of Pearson (1920). Pearson has shown that, in the case of tuberculosis, it is not the disease but the diathesis which is inherited, not the seed but the soil; that the death rate from disease is selective in a large percentage of cases, and that a higher infantile death rate implies the survival of a stronger and more enduring stock. He asserts that the trend of modern medicine to preserve the dis-

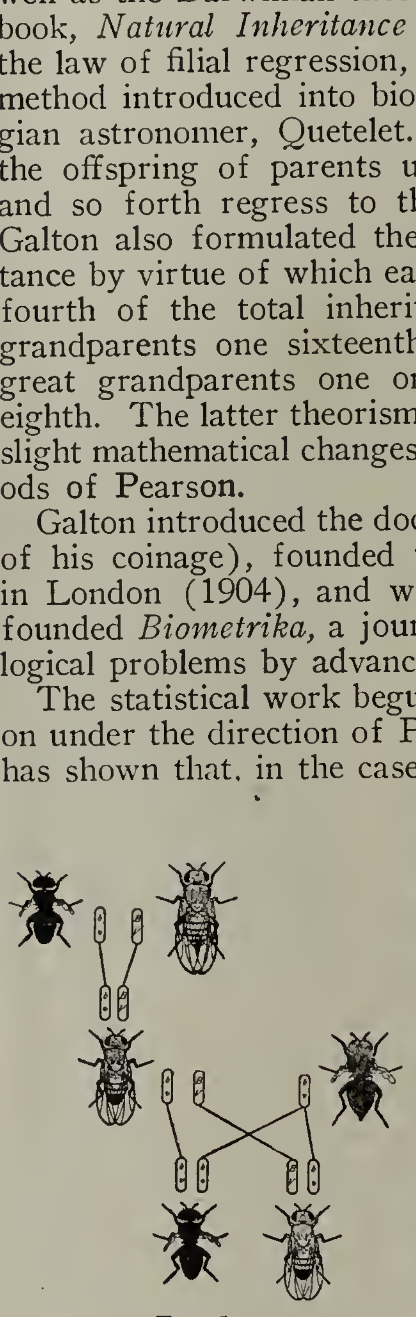

Fig. 5.

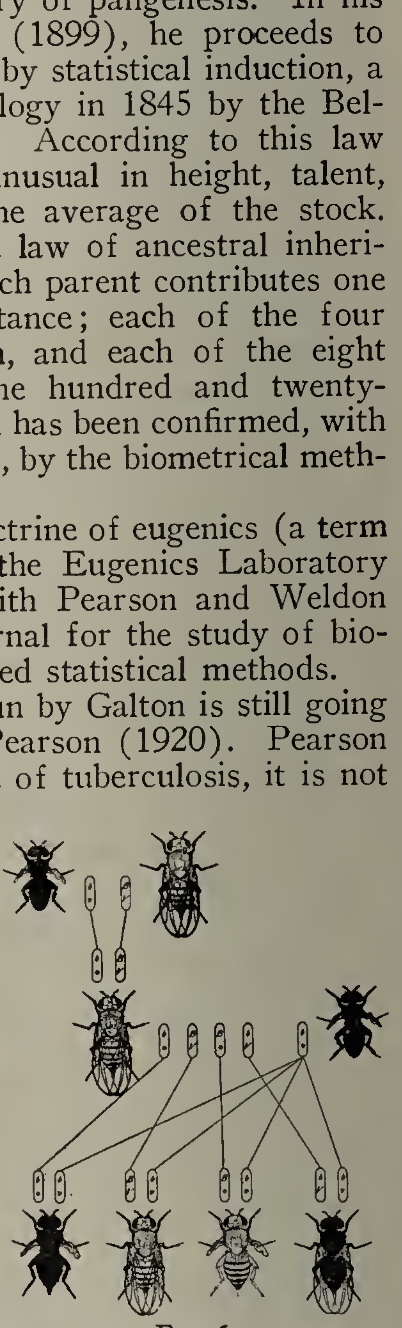

Fig. 6.

eased and deformed is not only detrimental to the human species, but can only be obviated by preventing the defective from breeding their kind. He asserts that dark eyed women procreate faster than the light eyed; and the tall faster than the short. He has established the law of assortative mating, by virtue of which human beings mate, not as usually believed, with their opposites in stature, complexion, and so forth, but with their own kind. In this respect he finds husband and wife are more alike than uncle and niece or first cousins.

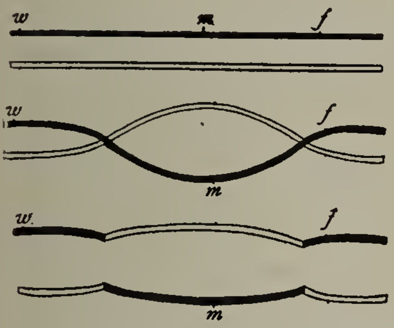

Fig. 7.—Scheme to illustrate double crossing over between white and forked. The gene for miniature standing between furnishes the evidence. (After Morgan.)

In the years immediately preceding the work of Mendel, important studies on the nature of hybrids were made by Naudin (1852). Naudin made a comprehensive survey of the facts of hybridization in plants and almost reached the point of expressing the generalizations which Mendel set forth a few years later. He pointed out the fact, first observed by Kölreuter, that hybrids may be brought back to the form of either parent by repeated crossing with a parent. Naudin supposed that these potentialities might become segregated in the pollen grains and ovules of the hybrid plant. Naudin, however, never conceived of the genetic possibilities of the hybrid character.

A review of the theories of heredity would be very incomplete without a brief study of Mendel. Johann Mendel (Fig. 1) was born July 22, 1822, at Heinsendorf bei Odrau, in the "Kuhland" district of Austrian Silesia. His father, a peasant proprietor with small holdings, took special interest in fruit culture, and initiated Johann at an early age into the methods of grafting. The name Mendel connotes Jewish origin, but it is practically certain that the suggestion is without foundation. The family name appears in the Church Register of the seventeenth century, usually as Mandel, whereas it was not until the reign of Joseph II (1765-1790) that the Jews in Austria assumed definite surnames.

Mendel's maternal uncle conducted private classes for the children of Heinsendorf who could not walk so far as the neighboring village, for in Heinsendorf itself there was at that time no regular school. Mendel later attended a government school established on the death of the uncle. His talent was noticed and encouraged by the master. At this time also two older boys who had gone away to the school at Leipnik fell in with Mendel during their holidays and excited his ambition, with the result that he asked his parents to let him study. When eleven years of age he, too, was sent to Leipnik, although this involved considerable sacrifice on the part of the family. Here he distinguished himself so much that it was decided to continue his education at the gymnasium at Trappou, a course which finished with a year at Olmutz. The parental resources were severely taxed by such expenses, and Mendel was only enabled to complete his course through the generosity of a younger sister who voluntarily contributed a part of her dowry for this purpose. In after years Mendel repaid her advance many times by providing for the education of his three nephews.

At Trappou, one of the teachers was an Augustinian monk, and it has been surmised that perhaps his description of the scholarly tranquillity of the cloister may have turned Mendel's thoughts towards a monastic life. However that may be, when his course at the gymnasium was ended he became a candidate for admission to the Augustinian house of St. Thomas in Brunn, an institution generally spoken of as the Königskloster. His application was successful and he was elected with a view to his taking part in the educational work which then devolved on the institution. On admission, he took the name of Gregor "in religion," Johann being his baptismal name. In 1847 he was ordained a priest.

At the expense of the cloister he was sent, in 1851, to the University of Vienna, where he remained until 1853, studying mathematics, physics, and natural sciences. During this time he published two notes on Scopolia margarilis and Bruchus pici. On his return to Brunn he became a teacher, especially of physics, in the Realschule. He appears to have taken great pleasure in teaching and to have been extraordinarily successful in interesting his pupils in their work. He continued this occupation until 1868, when he was elected Abbot, or more strictly Prälat, of the Königskloster (Fig. 1).

The experiments which have made his name famous throughout the world were carried on in the large garden of the cloister. From the time of his novitiate, he carried on experimental work, introducing various plants into the garden, and watching their behavior. He was very fond of showing his experiments to his friends. Dr. von Niessl relates how on one occasion he was taken to see Ficaria calthaefolia and Ficaria ranunculicides which had for some years been cultivated side by side without manifesting any noticeable change. Mendel jokingly said, "This much I do see, that Nature cannot get on further with species making in this way. There must be something more behind."

Mendel did not find himself in full agreement with the views of Darwin, which at that time were coming into prominence, and to justify his opinions he embarked on his experiments with peas which he continued for eight years. The results were communicated to the Brunn Society in 1863 and published in 1866, but they passed unheeded. The subsequent paper on Hieracium appeared in 1869, and met a similar fate.

During this period of scientific work Mendel was engaged in a great variety of research. In his letters to Nägeli, there are allusions to some of these subjects, but unhappily few statements of results. His largest work, with the exception of that on peas, was an investigation of the heredity of bees. He had fifty hives under observation, and collected queens of all obtainable races, European, Egyptian, and American. Although he effected numerous crosses between these races, it is known that he had many failures. The notes which he was known to have made on these experiments cannot be found, and it is supposed that they were destroyed during one of the periods of depression from which he suffered during the latter part of his life.

For many years Mendel attended closely to meteorology and published his records annually in *Brunn Abhandlungen.* He also took a great interest in sunspots, drawing them, recording the frequency of their occurrence, and making such other observations on them as he could by simple means. He was among those who inclined to the view that there is a connection between the spots on the sun and meteorological phenomena.

Mendel served a term as president of Naturforscher Verein in Brunn, and was chosen chairman of the Moravian Hypothekon Bank. He was also a skilled chess player, and composed many problems which, however, were not published. In Heinsendorf, his native village, he is remembered as having been the originator of a fire brigade. When he eventually became famous, the erection of a new fire station was used as an opportunity of commemorating him, and a memorial tablet was placed on the façade.

The total neglect of Mendel's work is known to have been a serious disappointment to him, as well it might have been. He is reported to have had confidence that sooner or later it would be noticed, and sometimes said, *"Meine zeit wird schon kommen!"*

With the possible exception of Nägeli, none of the leading naturalists of the time ever saw the paper on peas.

Mendel's researches practically ended at the time of his appointment as Prälat of the Königskloster. He wrote Nägeli, at the time, that he hoped that after an interval his elevation might enable him to find better opportunities for study. In 1872, the government passed a law imposing a special tax on the property of religious houses. This enactment Mendel conceived to be unjust, asserting that all citizens should be equal in law, and that if these taxes were imposed on one class of institutions they should be imposed on all. At first several other monasteries stood out with the Königskloster, but gradually they conformed to the requirement of taxation. Mendel alone remained firm. The quarrel involved him in protracted trouble and litigation, which took up almost all of his time. The property of the house was eventually distrained, but he did not yield. He also became involved in the racial controversies which are often in evidence in Austrian Silesia, and it is only too certain that the last ten years of his life were passed in disappointment and bitterness. From being a cheerful, friendly man, he became suspicious and misanthropic. During this period he contracted chronic nephritis of which he died January 6, 1884. It is interesting to know that a few years after his death the tax was removed without debate or dispute.

Until 1900 only one reference to Mendel's observations appeared in scientific literature; namely, that in Focke. Reference was also made to Hieracum in this article. It was through this reference that, in 1900, de Vries of Belgium, Correns of France, and Tschermak of Austria, wrote papers giving the substance of Mendel's long unnoticed treatise, and each one confirmed and extended Mendel's conclusions.

De Vries observed in the evening primrose that new types seemed to arise suddenly; these bred true, and thus gave rise to new species, which he called mutations. In the exposition of his theory he states, "Species have not arisen through gradual selection, continued for hundreds or thousands of years, but by jumps through sudden, though small, transformations." This theory was at variance with the theory of Darwin who supposed that slight individual variations are probably the sole differences which are effective in the production of new species. Natural selection acts solely by accumulating slight, successive, favorable variations; it can produce no great or sudden modifications. De Vries contended that natural selection presides over and improves variation arising from sudden changes.

Recapitulation theory.—After the advent of the cellular theory and during the early work on plant hybridization the recapitulation theory arose. According to this theory animals are supposed in their individual development to recapitulate to a considerable degree phases of their ancestral history. This was suggested in the writings of von Baer (1827-1876) and Louis Agassiz (1857-1862), but received its first clear and complete expression in 1863 in the writings of Fritz Müller. This theory was the dominant note in all of the speculations of Balfour (1873-1882), and received its most sweeping application in the works of Ernest Haeckel. This theory is still adhered to by various authors.

The synthesis of the old views.—All the theories advanced have been more or less synthesized into our modern views. The problem of inheritance today so far as it can be elucidated by structural studies has come to be recognized as a problem of cellular life. Hertwig, Fol, van Beneden and Strasburger solved the longstanding riddle of the fertilization of the egg and the mechanism of hereditary transmission. The identification of the cell nucleus as the vehicle of inheritance, because of the behavior of the chromosomes, was made independently and almost simultaneously in 1884-1885 by Oscar Hertwig, Strasburger, Kölliker and Weismann. Huxley characterized protoplasm, simple or nucleated, as the "physical basis of all life." Today Morgan characterizes the chromosomes as the physical basis of heredity.

The ideas of Haller, Bonnet, and others are found in the theory of inherited organization as an expression of germinal continuity and are vastly different from the old theory of preformation.

The theory of epigenesis, as expressed by Wolf, has been modified to include the conception of prelocalization of hereditary qualities within particular parts of the egg. It has come to mean that development is a process of differentiation of certain qualities already laid down in the germinal elements. The necessity of all hereditary qualities being combined within the egg and sperm was seen early by Darwin (1831-1882). To satisfy this indispensable condition he presented the theory of pangenesis, which had been conceived and combated by Aristotle many centuries before. This theory rested on the supposition that minute particles, which Darwin called gemmules, were set free from all the cells in the body; those of the muscular system, of the nervous system, of the bony tissues, and of all other tissues. These liberated gemmules were supposed to be aggregated within the germinal elements (ovum and sperm). The germinal elements, therefore, would be a composite of substances derived from all organs and tissues. Spencer (1820-1903), reasoning somewhat along the same line, supposed that there were structural units of protoplasm comparable with molecules of chemical compounds; these socalled physiological units within the body he supposed to be composed of a different kind or kinds of units. Distinct traces of these theories are seen in the ideas of Weismann, but explain the fundamental construction of a single type of cell instead of cells in general.

From the time of Buffon until the modern era many theories have been advanced concerning the influence of environment on development. The views of Darwin held sway for many years, but the most satisfactory interpretation of environmental influence on subsequent generations has been demonstrated as a side development of King's carefully conducted work on rats. King has shown that improper nutrition and laboratory surroundings through four successive generations did not permanently impair the growth of the individuals which responded at once to the stimulation of a well balanced diet and proper laboratory surroundings. The rats in the fifth and in the sixth generations grew much more vigorously than their forefathers, and many of them attained an adult size equal to that which is normal for the albino rat. The work of Kammerer on the effects of environment on a particular organ has given definite results. He studied the effects of a gradual return to daylight on the young cave salamander. The animal developed normal eyes and at the same time pigmentation of the skin returned. The numerous studies which have been conducted on the relation of environment to development justify the assumption that the effect is parallel in somato plasm and germ plasm. With return to the normal habitat, the effects of untoward environment disappear and the individual assumes the characteristics of the species to which it belongs.

Continuity of germ plasm.—The basis of heredity today rests on the theory of germinal continuity. Briefly, germinal continuity means that the ovum and its fertilizing agent are derived by continuous cell lineage from the fertilized ovum of previous generations, extending back to the beginning of life. This was first clearly set forth by Virchow who demonstrated that cells both in health and in disease arise only by the growth and division of previously existing living cells, and to express this truth he coined the formula *"omnis cellula e cellula."* It was necessary to establish this law of cell succession before any idea of germinal continuity could prevail. Virchow's work in this connection is of undying value. When the theory of the continuity of living substance was applied to inheritance, a distinction between germ cells and body cells was demanded. It was not, however, until the period of Balfour, Fol, van Beneden, Boveri, Hertwig, and others that the great importance of this need began to be appreciated.

Brown, the discoverer of the nucleus of the vegetable cell, pointed out, in 1849, certain differences between body cells and germinal elements, but did not follow up the distinction. The idea was also forecast by Haeckel in his *General Morphology*. In 1875, Nussbaum clearly stated that the germinal substance was continued from unbroken generations of the past and was the particular substance in which all hereditary qualities were included.

The theory of the continuity of the germ plasm found its most ardent exponent in Weismann (Fig. 2). His teachings were based on the knowledge that all animals, even the highest, begin life in a fertilized egg. This structure, minute as it may be, must contain all the hereditary substance, as it is the only material connection that exists between generations. This hereditary substance, or germ plasm, is the living, vital element of an organism that takes part in the development of a new organism. Weismann pointed out that the many celled body was gradually produced by evolution and that in the transmission of life by higher animals the continuity is not between body cells, but only between germinal elements which represent the primordial substance around which the body has been developed. In all the long process of evolution the germinal elements have been the only form of connection between different generations, and so their continuity has remained unbroken.

The fertilized egg cell of an animal begins its development by dividing into two cells; these divide into four, and so forth. The newly forming cells are not all alike; some develop into muscle, others into bone, or nervous tissue. In short, they become differentiated to form the various parts and tissues of the body, except that a few remain undifferentiated like the original egg cell itself and give rise to egg cells or sperm cells. Weismann called the cells which collectively make up the body the soma cells, whereas those undifferentiated cells destined for reproduction he called germ cells. He maintained that the germ cells, since they are not descended from body cells but only from the fertilized egg cell, have no way of transmitting body modifications, that is, acquired characters. The germ cells are guests in the body, but not members of the household. To show the separateness of germ plasm and somato plasm, Castle transplanted the ovaries from a black guineapig into a pure albino female and crossed with a pure albino male. The six offspring were black. Body cells and germ cells are morphologically distinct, and, therefore, heritable variations cannot have their origin in body cells, but only in the germ plasm. The egg and sperm cells are the sole vehicles of inheritance, and the final unit of the transmission of hereditary characters is the chromosomes, which were first recognized by van Beneden.

The rationale of the theory of Weismann rests in its consideration of the impressionable nature of protoplasm; in fact, the most characteristic property of protoplasm is its response to stimulation. The modifications and subtle changes which result affect its organization, and in the final status are the result of the summation of experiences. Two masses of protoplasm differ in capabilities and potentialities according to the experience through which they have passed, and no two will be absolutely identical. When the body is built anew from the germinal elements, the fundamental qualities of the germ plasm come into play and the whole process is a succession of responses to stimulation. This is in a sense a repeating of historical experience on the part of the protoplasm. In building the organism, the protoplasm does not go over the ground for the first time, but repeats the activities which it took centuries to acquire.

The evident complexity of the germ plasm made it necessary for Weismann, in attempting to explain inheritance in detail, to assume the existence of distinct vital units within the protoplasm of the germinal elements. He invented names for particular units. The fundamental vital units are designated biophors; determinants or determiners are vital units made up of aggregations of biophors. It is on the biophors in determiners that the structure of the future individual depends. These units are often spoken of as genes or unit factors which give origin in the new individual to the socalled unit characters. Ids are made up of groups of determinants. The ids possess power of growth and multiplication. Idants are combinations of ids and are the same as chromosomes.

It was Weismann's opinion that the roots of all heritable variation lie in the germ plasm, that the determinants are continually oscillating hither and thither in response to minute nutritive changes, and are readily compelled to variation in a definite direction, which may lead to considerable variations in the structure of the species.

The life of Weismann is characterized by its lack of the unusual. He was born at Frankfurt-am-Main in 1834. He studied medicine at Göttingen. He was graduated in 1856, and for a short time practiced clinical medicine. As this did not satisfy him, he turned to microscopic investigation in embryology and morphology, in which work Leuckart encouraged him. In 1863 he settled in Freiburg as *privat docent* and, in 1867, was promoted to a professorship in the department of zoology, which he retained until his retirement a few years before his death. He was a forceful and interesting lecturer. After thirty years of age he had trouble with his eyes, but he was always able to do practical work. During the period of greatest distress his wife read to him and helped him in his practical and experimental work. Weismann was an accomplished musician and during his periods of enforced idleness derived a great deal of comfort from music.

The laws of heredity.—The prolonged endeavors of investigators of heredity have resulted in the establishment of certain principles which must be reckoned with in the classification of hereditary conditions, and in the attempt to prove unclassified conditions hereditary. Heredity has as definite a program for its understanding as has bacteriology, chemistry, or physics, and like these sciences it has come to signify a definite branch of learning. There is, therefore, no reason why the word heredity should continue to be used by physicians in discussing certain conditions in man in any sense except the correct one.

There are six laws and a corollary which have been found to govern matings. The first two were formulated by Mendel, and the others have been very clearly worked out by Morgan. The first law of Mendel is known as the "segregation of characters," and the second as the "independent assortment of characters." These laws are well illustrated in Fig. 4. The transmission of the colors or characters, red and white, clearly demonstrates the phenomena in heredity which Mendel interpreted as the segregation of characters. In simple terms this means the separation in the second generation of the identical characters present in the parental generation. Mendel also believed each character to be transmitted independently of all other characters. This may be true for the characters represented in Fig. 5, but sufficient evidence is available to warrant the statement that the second law is only true within as yet undefined limits.

The four other laws and the corollary are really explanations of the first law of Mendel and of reasons for a restricted acceptation of the second law. These laws are known as, 1, linkage; 2, linear order of genes; 3, interference, and, 4, limitation of linkage. The corollary to linkage is "crossing over."

Linkage is the union of groups of determiners in the germ plasm, and as a result certain pairs or groups of characters always appear in the same individual. When it has to do with the factor for sex, it is known as sex linkage. The proof of linkage, often spoken of as coupling and repulsion, although studied by many investigators, has been clearly worked out by Morgan and his coworkers on the fruit fly Drosophilia. If two flies belonging to this species, one with recessive mutant (sport) characters, black body and vestigial wings (Fig. 6), and the other with wild type body color (gray) and long wings, are mated, the offspring are of the wild type body (gray) with long wings. If one of the males of this crossing is back crossed to a black bodied vestigial winged female, the offspring are of two kinds only; one half have black bodies with vestigial wings, and the other half have gray bodies with long wings. In other words the two mutant characters, black body and vestigial wings, that went in together, have come out together, and their two normal allelomorphic characters, wild type body, color (gray) and long wings, have also come out together. There are no flies of the second generation that are black bodied and long winged, and none that are vestigial winged and of a gray body color, as would be the case if independent assortment took place. The characters, gray body with long wings, and black body with vestigial wings, are spoken of as linked.

Sex linkage.—The results of breeding in which this principle comes into play were studied by Wood and completely worked out by Darbishire, who found "When horned breed of sheep, the Dorset horned, in which the horns are well developed in both sexes was crossed with a hornless race, such as the Suffolks, both sexes in which are hornless, the result was that all male lambs of the first hybrid generation developed horns, whilst the female remained hornless. The result of reciprocal crosses was identical. It appears that the horned characters were dominant in males, but recessive in females. But this view is shown to express the truth imperfectly by the appearance in the second hybrid generation of horned ewes and hornless rams. The explanation of these phenomena, so far as it is an explanation, is found to be that a ram is horned both when he is heterozygous and homozygous, whilst the ewe is horned only when she is homozygous for it. That is why all the ewes in the first hybrid generation were hornless. In other words, a ram will develop horns with only one dose of the horned character, but an ewe needs the two doses which are only present in the homozygous condition of that character." An appreciation of the explanation of sex linked inheritance clarifies the method of inheritance of hemophilia and color blindness in man. These characters are considered to be sex linked.

Crossing over, the corollary of linkage involves a change in the mechanism of linkage. In illustration of complete linkage, the cases chosen were those in which entire chains of unit factors in the chromosomes remained intact during the reduction divisions. In some cases there is an interchange of blocks of genes between homologous pairs of chromosomes. This interchange is called crossing over, and refers to the behavior of chromosomes during the processes of fertilized ovular division. The evidence obtained by Morgan and his assistants shows that this procedure is not haphazard, but gives numerical results of extraordinary constancy. If a black fly (Fig. 6) with vestigial wings is crossed with a fly with gray body and long wings, the offspring of the first hybrid generation have gray bodies and long wings. If one of the females of this generation is back crossed to a male fly with black body and vestigial wings, the second generation consists of four kinds of offspring: 1, black body with vestigial wings; 2, gray body with long wings; 3, black body with long wings; and, 4, gray body with vestigial wings. The two latter flies are the expression of crossing over. Under fixed environmental conditions the percentage of crossovers is definite for a given stock of a given age.

The linear order of genes.—The evidence on which this law was established is furnished by linkage and crossing over. When three mutant characters, yellow, white, and bifid, were used by Morgan in a single experiment, it was found that there were 1,160 noncrossovers, fifteen flies representing single crossovers between yellow and white, and forty-three flies representing single crossovers between white and bifid. There were no double crossovers. The simplest way in which such a relation can be thought of is that the three genes stand in the chromosomes in a straight line. There is no other geometrical arrangement conceivable that can satisfactorily explain the occurrence. When double crossing over takes place between two characters y and B (Fig. 7), the two series that result as marked by their ends alone (y and B) are still y and B. The result would be considered as representing noncrossover.

Fig. 11.—Scheme representing another type of interference.

Interference.—One of the most significant results that a study of crossing over has brought to light is that whole blocks of genes go over together. This means pairs of linked genes do not act independently of their neighbors, but that a break in a chromosome with certain types of genes interferes with a break in other regions when the intervening block is of a certain length (Figs. 8, 9, 10, and 11). In lengths more or less than a certain standard no interference occurs.

Limitation of linkage groups.—According to Morgan the limitation of linkage groups depends on the number of chromosome pairs. The only species in which a correspondence that is numerically significant between the two has been proved is Drosophilia melanogaster. Despite the absence of other positive evidence, the fact that in no other animal or plant does the number of linkage groups exceed the number of chromosome pairs may be legitimately interpreted in favor of the view. Bateson is of the opinion that this hypothesis should be accepted with caution.

DISCUSSION.

The mechanism of heredity came into play with the appearance of bisexual life on the surface of the earth. Its laws will continue to function until such life becomes extinct.

The physicobiological characters which are transmitted to subsequent generations by means of the germ plasm, furnish the concrete basis for studies in heredity. A biological character signifies the possession of the physical and chemical composition by which individuals may be differentiated. Characters are rendered physically immortal by heredity, and the study of heredity becomes in consequence an investigation of the mechanism of physical immortality. Physical characters become extinct unless perpetuated by heredity. The vehicles on which the transmission of the characters depends are the nuclear structures, chrômosomes, in all germ cells, and in certain instances the cytoplasm of the germ cells. The hereditary substances in the chromosomes and the cytoplastic structures together comprise the germ plasm. The germ cells or gametes in man are the ova and spermatozoa.

Heredity never deals with the etiological factors for disease. Any characters appearing in man that can be proved hereditary are normal, biologically speaking, regardless of how they may make him unfit for harmonious cooperation in economic and social program.

By heredity the quantitative and qualitative characters in all bisexual species are kept extant and limited. Under similar conditions of reproduction, the numerical expression of the transmission of these characters follows very closely, or is reducible to, a fairly definite ratio. An hereditary character is always wholly hereditary, and not hereditary on a percentage basis.

The science of heredity includes the study of the intermediate as well as of the immediate stage of certain features of the life cycle. The ova and the spermatozoa form the intermediate stage of the life cycle in man. The rearrangement of chromosomes which occurs following their union furnishes the fundamental basis for the study of the tangible evidences of heredity in the immediate stage of the life cycle.

The term heredity as ordinarily used by medical writers means the presence of a like condition in parent and child. This occurrence is usually described as one of the etiological factors of the disease under consideration. This conception of the science of heredity is too limited and often results in the publication of data which in no way conform to the definite principles which invariably govern the transmission of hereditary characters.

The only laws of heredity that have been demonstrated in man are Laws 1, 2, and 3; in man of course there is no hybrid in the strict sense. The absence of the hybrid generation renders insignificant the terms dominant and recessive, as they are determined by the type of hybrid.[1]

Experimental Study of Immobility of the Diaphragm

By FRANK C. BALDERRY, M.D.,
Perrysburg, N. Y.,

At the suggestion and with the aid of Dr. John H. Pryor, an experimental study has been made of the etiology and effects of immobility of the diaphragm. Since 1916, when Dr. Pryor published his first paper on this subject, more attention has been given to this organ and its functions by both clinicians and röntgenologists.

Clinically it has been observed that certain conditions alter or suppress the action of the diaphragm. Its motion may be limited and its position high when the phrenic nerve is involved by systemic poisoning, pressure of tumors or abscesses, direct injury and injury or disease of the cervical region of the spine. Elevation and limitation of action are also found with ascites, accumulations of gas in the abdomen, abdominal tumors, peritonitis, subphrenic abscess, hepatic abscess, and perinephritic abscess. Pancoast has found that in the early stages of acute pleurisy this condition is present due to reflex action. In pulmonary tuberculosis with the lesion limited to the upper lobe, in aneurysm, emphysema, pneumothorax, pleurisy with effusion, empyema, myositis, and degenerative changes of the muscle, the diaphragm is observed in a low position and its normal excursion is limited or entirely absent.

Experimentally we produced immobility of the diaphragm by three methods: 1. Simple pleurisy with effusion—meaning by this an inflammation of the pleura with a serous exudate caused by an irritant and not due to bacterial invasion. 2. Pleurisy with effusion produced by the tubercle bacillus alone, or in conjunction with the staphylococcus. 3. Freezing the phrenic nerve with ethyl chloride. One hundred and thirty-five rabbits and twelve guineapigs were used. All were fluoroscoped before inoculation, and normal excursion of diaphragm noted. To be sure that the inoculation was intrapleural, the water manometer was used and a negative pressure with fluctuation of the column of water observed.

In the production of a simple pleurisy with effusion, twenty rabbits were given an intrapleural injection of five c. c. of twenty per cent. aqueous solution of peptone. This produced a rapid exudation of serum in the pleural cavity, usually of such an amount as to cause great dyspnea and embarrassment of the heart's action, necessitating the removal of the effusion by aspiration in from eighteen to twenty-four hours. Fluoroscopy of these animals during exudation showed an effusion upon the affected side (right side used in this series). The heart and mediastinal contents were displaced to the left. The diaphragm was in a low position and flattened, its normal convexity destroyed and motion absent. Inversion of the animal with the resulting gravitation of the fluid away from the diaphragm caused the diaphragm to resume its convex form and motion to be reestablished.

Undoubtedly, the weight of the abdominal organs and the fact that the intraabdominal pressure was positive were factors in causing the diaphragm to regain its normal convexity, but they were apparently not of sufficient importance to cause immobility of the diaphragm. No doubt the increased intrathoracic pressure acted as a balance, and permitted motion to occur. Removal of the fluid also permitted a resumption of diaphragmatic motion.

During this early stage, the pleura and diaphragm exhibited signs of an acute inflammatory process. The serous membranes were reddened, and the diaphragm showed a marked dilatation of its vessels.

Following two or three aspirations, the exudation ceased; and from the tenth to the twenty-first day, on examination of the animal by the fluoroscope, the diaphragm was found to be in a low position and motionless. These animals now appeared normal, except that the respiratory rate was increased and the respiratory movement upon the affected side was lessened. This increased rate, as well as a diminution of the amount of air inspired and exhaled, was shown by graphic records of the tidal air. These were obtained by using a revolving drum with smoked paper and an ordinary drinking glass, its opening covered with thin rubber, a rigid arm attached to its centre for recording on the paper the excursion of inspiration and expiration, and in the base of the glass an opening to which was attached a rubber tube with enlarged opening at the opposite end that fitted over the nose and mouth of the animal and through which they breathed.

At postmortem a retracted chest wall was seen. On opening the thorax little or no displacement of the organs was noted. Free fluid in the pleural cavity was not found but small amounts that had been encapsulated were in a few instances present. The heart was at times found slightly more to the right. The lung was found adherent throughout its lower half, but was usually free in the upper portion. It was normal in color and on section showed atelectasis. Adhesions were numerous and very heavy. Organization was complete and separation of the lung from the chest wall, diaphragm and mediastinal contents difficult.

These occur most frequently and are more dense in the costal sulcus, cardiac sulcus and between the lateral surface of the lower lobe of the lung and the pericardium. The next most common location is between lower surface of lower lobe and diaphragm.

In the costal sulcus from one to three bands were found between the chest wall and the diaphragm. Adhesions were not found between the diaphragm and the abdominal organs. The diaphragm was lower than normal, appearing usually as a straight line from the midline to the chest wall. It was slightly thicker than normal. At about the inner one third, we at times found increased connective tissue and contraction. The pleura was thickened. Atrophy of the muscle was found. There was wasting of the fibres with collapse of the sheath and increased fibrous tissue. Electrical stimulation of the phrenic nerve caused a contraction of the diaphragm.

In this series we had the diaphragm immobile from two separate causes. It was at first immobilized in a mechanical way by increased intrathoracic pressure and fluid. Later by reason of disease of the diaphragm muscle itself and the presence of adhesions. The results in this series were as follows: immobility of the diaphragm, one hundred per cent.; low position of the diaphragm, one hundred per cent.; adhesions greatest in the costal sulcus, twenty per cent.; adhesions greatest in the cardiac sulcus, eighty per cent.; temporary return of motion of the diaphragm after aspiration, ninety-five per cent.; response of the diaphragm to electrical stimulation, ninety-five per cent.; atrophy of diaphragmatic muscle, ninety per cent.; atelectasis of the lung, eighty per cent.

In the first of this series the pleurisy was produced upon the right side only. Forty-five rabbits were used. Two c. c. of distilled water containing virulent tubercle bacilli were injected into the pleural cavity. From the eighth to the tenth day the right chest on fluoroscopic examination showed a generalized haziness and the diaphragm functioning. At this time there were inflammatory changes in the pleura shown by congestion, dilatation of the vessels, swelling, a lack of normal lustre and slight exudation of fibrin. This was most marked toward the mediastinum and in the cardiac sulcus. The diaphragm was hyperemic and this inflammatory reaction was greatest at inner third. Haziness first noted under the fluoroscope gradually increased and, from the eighteenth to the twenty-fourth day, definite lung markings were observed with difficulty. At this time a slight effusion might be seen. This effusion accumulated slowly and varied greatly in amount, at times as low as five c. c. and again as high as twenty-two c. c. The fluid was usually bloody in character and rarely was it of an amber color. The leucocyte count was high.

Fluoroscopic examination disclosed a motionless diaphragm in practically all cases following the presence of fluid. Following the first aspiration, the diaphragm functioned. In two cases immobility of the diaphragm was found without an effusion ever having been present, but the diaphragm retained more of its normal contour and the position was not as low as was usually noted in those with effusion.

This shows that in certain isolated instances immobility of the diaphragm may follow a dry pleurisy. The low position of the diaphragm is greater than the lowest point reached in a normal respiratory excursion. The number of respirations is increased and the tidal air diminished.

At postmortem the chest wall was found retracted on the affected side. Slight bulging of the unaffected side was often noted due to the increased respiratory effort and compensatory emphysema. The intercostal muscles of the affected side were atrophied. On opening the chest after immobility was complete a variable amount of fluid was found dependent upon whether aspiration had been performed recently. The heart was usually displaced to the right as a result of the adhesions between the lung and the pericardium.

The lung was bound down in the lower half by adhesions, and the lower lobe showed an uneven surface and was contracted. Adhesions in the upper half of the chest were rarely found. The adhesions were greatest in the costal sulcus, cardiac sulcus and between the lung and the pericardium. In the costal sulcus there were usually one or two bands that extended from the diaphragm to the chest wall. There were also many fine threadlike adhesions between the lung, the chest wall and the diaphragm. That portion of the lower lobe found in the cardiac sulcus was very adherent to the diaphragm and pericardium. It was separated from these structures with difficulty. The lateral surface of the lower lobe was markedly adherent to the pericardium. This condition is always present and bears out Dr. Pryor's clinical findings. Interlobular pleurisy with the lower and middle lobes adherent to each other was found in sixty-five per cent. of the cases.

Involvement of the lung with tuberculosis was present in ten per cent. of the cases. This condition was usually found in the lower lobe in the periphery. Atelectasis of the lower lobe was marked.

The diaphragm was in a low position. It was adherent to the lung in the cardiac sulcus and frequently in the costal sulcus. Strong bands extended between the chest wall and the diaphragm. It was remarkable that it was not more often found adherent to the under surface of the lower lobe of the lung, and that these adhesions when present were not more dense. Adhesions between the diaphragm and the adjacent abdominal organs except in one instance did not occur.

The diaphragm was thicker than normal and its normal lustre had disappeared. Large deposits of fibrin were found on the upper surface, most marked at the inner third. This inner third was the location of the greatest thickening and was greatly contracted. The fibrin had become organized and the connective tissue was increased. The muscle fibres were wasted and the sheaths collapsed. Fibrous tissue was greatly increased, most marked at the inner third. The pericardium was adherent to the lung in all instances. It was thickened and roughened at this point. Slight pericardial effusion of a bloody character was found in twenty per cent. of the cases. The adhesions between these two structures were very great and were separated with difficulty. The area of greatest inflammatory action was in the cardiac sulcus and at the mediastinum. Electrical stimulation of the phrenic nerve caused contraction of the diaphragm.

In this series we selected twenty animals as showing immobility of the diaphragm and the results were:

Immobility of the diaphragm, ninety per cent.; low position of the diaphragm, ninety per cent.; adhesions greatest in the costal sulcus, twenty-five per cent.; adhesions greatest in the cardiac sulcus, seventy-five per cent.; response of the diaphragm to electrical stimulation, ninety per cent.; atrophy of diaphragmatic muscle, ninety per cent.; increased connective tissue, ninety per cent.; atelectasis of the lung, ninety per cent.; return of motion after first aspiration, eighty-five per cent.; respirations increased, tidal air decreased, ninety per cent.

In the second series both pleural cavities were inoculated at once. In those instances where the effusion upon one side did not develop, the animal was reinoculated upon that side. Forty-five rabbits and twelve guineapigs were used in this series. Guineapigs were found unsuitable for the work, because of their weak mediastinum, death resulting from its rupture. It is not necessary to go into details as the results were much the same as those described previously, but there are certain findings that are of importance.

Dyspnea was more marked and the breathing extremely labored. Respirations were increased in rate and the tidal air decreased. In the early stages general haziness of the entire chest was found. This gradually increased till slight effusion might be observed. The diaphragm remained functioning until effusion had formed in all but four cases. In these it was not a bilateral immobility, but occurred on the right side only. After immobility of both leaves of the diaphragm, it appeared as an inverted letter V with the apex at the ensiform cartilage. The costal and cardiac sulsi were wider than normal due to the descent of the diaphragm. The heart appeared to be in the midline and the apex was more toward the midline. It was narrower than normal and pulled down, assuming a tubular shape. Between the heart and the diaphragm a clear space was seen. Changes noted at postmortem showed that this condition was not entirely respiratory, but also affected the circulatory system to a great extent.

The changes in the lung and diaphragm and the location of the adhesions were the same as when the pleurisy was upon one side only. The pericardium was duller in color and tense on account of the downward pull caused by its attachment to the diaphragm. It was thinner than normal except at the points where it was adherent. There we found a thickening with a large increase of granulation tissue. In a few instances tubercles were found. On opening the pericardium slight effusions of from one to three c. c. of bloody fluid were found in fifteen per cent. of the cases. The heart was smaller than normal and was not of normal shape. When the disease was of long standing the heart appeared tubular. Its normal contour had disappeared. The apex was not found in its normal position on the left, but was displaced more toward the median line. The heart was slightly broad at its base, but almost normal. It appeared narrower and elongated. It had apparently been compressed by the pericardium as a result of the descent of the diaphragm exerting its pull upon the pericardial sac. There was a slight increase of fat in the heart and the muscle fibres show changes indicative of myocarditis and atrophy.

Electrical stimulation of the phrenic nerve caused a contraction of the diaphragm. Twenty animals were used in the series and the results were: Immobility of the diaphragm, eighty per cent.; low position of the diaphragm, ninety per cent.; adhesions greatest in the costal sulcus, twenty-five per cent.; adhesions greatest in the cardiac sulcus, seventy-five per cent.; adhesions between the lung and pericardium, one hundred per cent.; response of the diaphragm to electrical stimulation, ninety per cent.; atrophy of the diaphragmatic muscle, ninety per cent.; increased connective tissue, ninety per cent.; atelectasis of the lung, ninety per cent.; motion returned after the first aspiration, eighty-five per cent.; respirations increased and tidal air decreased, ninety per cent.

In the series of tuberculous pleurisies, 102 animals were used. Twenty animals were selected as showing immobility of the diaphragm either unilateral or bilateral. Ten animals were killed in these experiments after periods of from ten to fourteen days giving us the beginning inflammatory stage with a functioning diaphragm. Those in which a fixed diaphragm developed were killed from the twenty-seventh to the eighty-fifth day. Thirty-five of the animals did not manifest effusions. The early inflammatory stage was most marked in the mediastinum, cardiac and costal sulci. That there were early changes in the diaphragm was proved by the dilatation of its bloodvessels at an early stage. It was not alone pleurisy with effusion, adhesions or paralysis, but a gradual involvement of the diaphragm muscle itself. The formation of the fluid depressed it, the increased sediment in the sulci fixed it and maintained it later in a low motionless position. The circulatory system was influenced primarily, because we were dealing with an infectious condition; and, in the later stages, because of compression of the heart by either the fluid in the pleural cavity or the presence of pericarditis with effusion, these factors resulting in changes in the myocardian. In one instance, the paradoxical movement of the diaphragm was noted in which the leaves moved in opposition to each other. In this case the right pleura contained a small amount of fluid with the dome of the diaphragm in a higher position than normal and the left leaf greatly depressed.

In the production of immobility of the diaphragm by freezing the phrenic nerve, the nerve was exposed in the neck of the animal and ethyl chloride was applied for a period of one minute and thirty seconds. This covered the nerve with a coating of frost that persisted for about forty-five seconds following the discontinuance of the application of ethyl chloride. Immediately following the operation, less motion of the diaphragm was observed. At the end of ten hours motion was entirely absent. In this condition the diaphragm was in a high position of paralysis and its normal convexity was increased. The height of the dome was greater than during normal expiration.

On cutting the phrenic nerve, immobility and elevation of the diaphragm were immediate. Severing both nerves caused death. After cutting one nerve it was possible to influence respirations by irritation of the opposite nerve. Attempts to freeze both phrenic nerves at one time resulted in the death of the animal. Readings of the water manometer following freezing of the phrenic nerve showed an increased positive pressure. The immobility of those with frozen phrenic nerves persisted from five to seven weeks, when motion could again be observed. Electrical stimulation failed to bring on a contraction of the diaphragm from the tenth to the fortieth day. The lungs were normal except for slight atelectasis in the lower lobe. The diaphragm muscle showed atrophy of the muscle fibres with wasting, shrinking of the sheaths and changes in the nuclei.

It is our intention to produce pulmonary tuberculosis in animals and treat them by freezing the phrenic nerve, in the hope that it may influence the disease by causing less respiratory action of the lung. This procedure has been employed by a few German authorities in the treatment of pulmonary tuberculosis as a substitute for artificial pneumothorax. Good results are reported. It was our original plan to present work upon the prevention of this condition. In making our report on the series of tuberculous pleurisies we selected only those animals showing immobility of the diaphragm. It was our intention to treat the other animals as effusions developed with the aim of saving the motility of the diaphragm. Because of an epidemic that caused the death of practically all these animals, we were able to treat only a few.

We selected artificial pneumothorax as our first procedure in the hope that this would limit the formation of adhesions. By the use of some gas that might kill the tubercle bacillus or inhibit its growth, it was desired to shorten the duration of the disease. Air was at first used, but it was not found practical because of its rapid absorption. It was interesting to note that in normal rabbits introduction of sixty c. c. of air caused marked dyspnea and cyanosis. After twenty or thirty minutes dyspnea was still present but much less marked, and cyanosis had disappeared. In from twelve to twenty-four hours the animal appeared normal and a pneumothorax could not be observed.

It has been found that carbon dioxide in the proportions of three to one hundred of air has an inhibitory effect upon the growth of the tubercle bacillus. We used it in the ratio of three and five parts of carbon dioxide to one hundred parts of air. Too rapid absorption of the mixture was again encountered. A mixture of sulphur dioxide and air was tried and found to be less readily absorbed, and so was used in the treatment of five animals in which pleurisy with effusion occurred. The fluid was removed from these animals at various intervals dependent upon the extent of its accumulation.

At the time of aspiration, refills of the chest were made. These had to be repeated often because of the absorption of the mixture. The average number of treatments given was fourteen. These were given each day. Fifteen c. c. was usually introduced. The amount of sulphur dioxide varied from one part in one hundred to one part in three thousand of air. The exudation was apparently not increased by the use of a mixture of one part to one hundred. This did not produce cyanosis and dyspnea was mild. It was not possible to aspirate the entire amount of fluid in the chest. Fluoroscopy following aspirations always disclosed fluid in the costal sulcus. Of the five animals treated, in one an immobilized diaphragm did not develop; one was in a low position with greatly restricted excursion, and in the three remaining animals immobilization took place.

Freezing the phrenic nerve in those rabbits with pleurisy caused the diaphragm to assume a high position and to be motionless. The diaphragm became fixed in this position; the formation of adhesions was not influenced so that the procedure was discontinued, as it held forth no promises of saving the motility of the diaphragm.

Artificial pneumothorax seems to hold forth some promise as a therapeutic measure. Weil, who has used artificial pneumothorax in the treatment of pleurisies with effusion in an attempt to save the motility of the diaphragm, believes strongly in this procedure. He also says that "electrization of the diaphragm and of the phrenic nerve has not furnished different results."

We agree with Corper and Rensch that pleural effusions are as likely to occur in normal rabbits without previous sensitization as in those animals that have been sensitized. We also find the areas of inflammation most marked at the mediastinum, pericardium and inner third of the diaphragm. That this could be expected in animals seems rational to suppose, since the fluid will gravitate to the lowest point. Slight motion may be noticed in the diaphragm after complete immobilization. This is due to the movement of the ribs and intercostal muscles. Because of the adhesions between the diaphragm and the chest wall and the increased connective tissue formation in the diaphragm with subsequent contraction, complete immobilization does not occur until retraction of the chest wall is present.

That the effects of immobility of the diaphragm are not limited to the respiratory system is shown by the changes in the heart and pericardium. The parietal pericardium always discloses inflammatory changes, and there is very often pericarditis with a small amount of exudation. Changes in the heart muscle are frequently present. The involvement of this organ and its covering undoubtedly has a very direct influence upon the clinical symptoms of rapidity of pulse rate and dyspnea. Paralysis of the nerves of the diaphragm as a cause of immobility and low position of the diaphragm is unlikely, for with paralysis, the muscle assumes a high arch. Response of the diaphragm to electrical stimulation proves that the nerves were not involved.

The cause of immobility of the diaphragm is probably not due to one particular condition. Mechanically, the presence of fluid places it in a low immobile position, but decreasing the intrathoracic pressure by aspiration permits it to function again. In this connection one authority states that increased intrathoracic pressure must be present before there is descent of the diaphragm. In this we do not fully agree, as there are in a small percentage of instances immobility and low position without the formation of effusion.

The increased deposit of sediment in the sinuses and the many thick adhesions that result are also not alone the cause. Early involvement of the diaphragm with later changes in its structure probably plays the most important rôle. We feel that this disease of the diaphragm in conjunction with the effusion and adhesions is the cause of its immobility and low position. A careful search of medical literature has revealed few instances in which a postmortem study had been made of the diaphragm. The pathological findings correspond to our own insofar as structural changes in the diaphragm are concerned. It is our plan to continue this work giving particular attention to the matter of treatment, and we hope to be able to suggest a method that may in the great percentage of cases prevent this condition.

General Theory of the Neuroses

Concepts of the Theory

PART I

By ALBERT POLON, M.D.,
New York.

PSYCHOLOGICAL APPROACH.

One of the distinguishing features of the psychoanalytical theory of the neuroses is its psychological approach to mental and bodily symptoms of functional diseases. This viewpoint has been evolved in order to account for pathological phenomena which do not lend themselves to a satisfactory explanation by the application of the concepts of anatomy and physiology; also to meet a need which has not been filled by descriptive psychiatry. This approach does not limit itself to description but aims at the origin, mode of genesis, and the meaning of symptoms.

In respect to this approach, this theory shows a deviation from the tradition of medicine and psychiatry. The mental attitude which it implies is strange to one who has been trained to view clinical phenomena in terms of cellular activity and topical organ localization. Equipped with these means alone one finds the investigation of neurotic disease practically fruitless, since the crucial question is why and for what did the mental symptoms arise, and not as to what are their anatomical and physiological substrata.

The example of a hysterical phobia—called agoraphobia, will illustrate this point. The patient is scrupulously avoiding open places—wide streets, squares, and what not. He runs away from them as if they were a source of danger for him. For the somatist the only interest is in how the man is running away. What are the various neuromuscular mechanisms at play? To answer this question implies an enormous amount of research valuable in its special field, but it is useless to answer the question why the patient runs away. And yet there is a cause for his behavior. The causal connection can be expressed only by the recognition of the fact that the man appreciates danger. In other words the situation generated a psychological process which evoked motor activity. That is the reason he fears and flees from the particular place.

There are various other aspects of this symptom, which would be impossible to account for in terms of somatic function. Let us consider the case of the man who fears open places under particular circumstances, for example, when there are only few people and vehicles about. Why this apparently paradoxical reaction? The answer to this can again be obtained only by an investigation of the psychic process underlying the symptom. We would then learn of special considerations which guide the man's behavior under the particular conditions. We would find that the psychic process operative in this instance presents two phases. On the one hand this man's actions would in a measure correspond to the typical reactions of all human beings, and on the other his actions would be determined by motives which arose from his individual experience. Certain things acquired a particular meaning for him. His mental presentation of what constitutes the need for flight is differently associated from that of the average person. The finding of these individual elements in the mental process constitutes the prominent feature of the modern psychological approach. All these considerations which hold for the functional phenomenon with motor activity apply with especial emphasis when we deal with what one would call the pure mental symptom of a compulsion neurosis, designated also obsession. Neurophysiology and psychophysics can not even attempt to throw light upon this intricate phenomenon. There is nothing known in the soma of a compulsion neurotic that could account for the appearance of this symptom or for its particular morphology. The insight as to why it came about, why it has this particular form, and what it does in the economy of the mental life of the subject can only be obtained by an analysis of the psychological processes which generate these ideas. Also in this instance we would learn that in some respects the compulsion ideas follow the rules of typical thought and that in others they constitute an individualistic psychic reaction to special experiences, accounting for their deviation from the normal.

From these remarks we may gather that the essential of the psychological approach consists in dealing with mental phenomena in terms of their own category. In this procedure we avoid an explanation of the manifestations of the mind on an anatomico-physiological basis, as one would avoid seeking to explain digestion of proteins on the ground of a psychic mechanism. The empirical data of the neuroses with which this theory deals are the phenomena of consciousness.

PSYCHIC DETERMINISM.

Agreeing upon the validity of this material, psychoanalysis proceeds with it in exactly the same manner as any other branch of science with its material. It first aims at an exact identification of facts—it describes them. It next correlates them in the light of certain concepts, which are most helpful for correlation. And finally from the obtained concepts it formulates the theory which could account for all the phenomena coming under its scope.

Now the fundamental concept of all science is causality. Without it scientific investigation would be only an accumulation of facts, or only description. The correlation of data forces the necessity for a causal connection. One then views any given fact as a link in a causal chain. That which is, was produced by something before it, and again this given fact shall in its turn be the source of genesis for subsequent facts.

It is this principle of causality which constitutes the second distinctive characteristic of the psychoanalytical approach. Every element of mental life, whether an idea, feeling or connative state, implies a previous psychic state with which it is causally connected. It is determined by elements which have generated it, and in its turn it will result in further psychic manifestations.

Naturally we have no difficulty in seeing psychic determinism in phenomena in which the motive as an operating agency is clearly evident, as in the transparent cases of consciously directed thinking and in intentional acts.

But this causal connection is present also in those events which appear spontaneous and accidental, and of which there is no evident relation with the surface content of consciousness. In other words, causality operates also when they appear as irrelevant or actually contradictory to intention, as if they originated in another person. This strangeness and irrelevance constitute an important characteristic of several groups of mental phenomena, among which the most significant for our consideration is the neurotic symptom. An investigation would show that that which seems to be outside of the causal sequence of events is in reality definitely determined.

The problem may perhaps be put this way: Ordinarily man's thoughts and actions are clearly seen to be sensibly connected with each other. For every new step there are enough accountable reasons constituting the motive. Suddenly we find that this orderly sequential series is interrupted. There appears a gap between one point of consciousness and the next one. Between the two the gap is bridged by the strange and irrelevant thought or action.

This is the quality possessed by such phenomena as symptomatic acts, dreams, neuroses, psychotic episodes and neurotic character features. Let us consider the symptomatic acts. Under this term are embraced unintentional acts occurring in the normal. They vary from unimportant errors of speech, writing, reading, misperception to manifestations of a more serious consequence, such as mislaying or losing of things, or of forgetting to carry out weighty decisions.

In all these instances analysis would reveal that they were produced by motives of which the subject was not aware, but which nevertheless asserted themselves. In this light an error not due to ignorance turns out to be as much of an intentional act as the one which is readily acknowledged as such. A case of a misspoken word, for example, would show that into the conscious stream directing the speech there entered another factor, another motive which should have been excluded for reasons of either logic or expediency. The other motive, contradictory to the one inducing the speech, breaking through its barrier obtrudes itself upon the word to be used correctly, and deforms it in proportion as it succeeds in making it express not only its proper connotation, but also the one imposed by the intruder. The error in speech expresses both that which should have been said as well as that which should not. To give an example quoted by Freud: A lady by way of admiring the hat of another says: "I am sure you have messed up this charming hat yourself." The word "messed" expressed the thought "this hat is a mess," but it also clearly implies the proper word "made." Or the slip of tongue of an energetic lady who states: "The doctor said my husband did not need any diet. He should eat and drink whatever I want." The error in the word "I" voices the intruding tendency of the lady to assert herself even in food needs of her husband. But then it clearly has the connotation of "he."

The striking feature of these errors is that they express in a condensed manner two contradictory motives. The psychological mechanism which gives them their configuration is condensation. Their genesis is due to the breaking through of a tendency which should have been repressed for the occasion, in other words, inadequate repression. Conflict of motives and inadequate repression brings about the symptomatic act. In the light of these concepts the error has a meaning and a definite place in the causal series of mental life. Contrary to the prevailing notion, it is not an exception to the law of psychic determinism.

THE UNCONSCIOUS.

There is an important implication necessarily involved in the finding of the study of errors. One is that since a motive may be effective without being registered in consciousness, the conclusion is unavoidable, that "psychic" is not identical with consciousness. The realm of mental function extends beyond those registered in awareness. The mind which reveals itself as attuned to real situations, in terms of evident motives, constitutes only a cover, an upper stratum of the psyche, a net resultant of several conflicting factors, which have thrown upward some of the material in the form of consciousness. Under it are present unconscious psychic forces, which are in a state of tension ready to obtrude themselves upon the surface. In brief, there is an unconscious dynamic mentality.

We thus come to the consideration of the unconscious, the concept of which is indispensable for any sort of an orientation in the phenomena of neurotic, as well as normal mentality. Together with the principles of psychological approach and psychic determinism it constitutes the cornerstone of the psychoanalytical theory. Historically, it has been evolved from the study of functional nervous disease, but it is in the phenomenon of dream that it accords the best opportunity for its investigation. Let us briefly review what psychoanalysis of the dream has shown of its nature and what bearing it has upon the unconscious.

The dream viewed psychologically reveals itself as a psychic reaction of the state of sleep to disturbing stimuli, whether they arise externally or within the organism. The sleep itself in such an approach is regarded as a condition into which the mind retires, by withdrawing all its interests from the outside world. To fall asleep is to become selfsufficient; it is to become the source of one's excitations and of their gratification at the same time. It is to preserve this blissful selfsufficiency, which is so much like the intrauterine condition of the fetus, which constitutes the purpose of the dream. Contrary to the popular notion the dream is the guardian of sleep.

The disturbing factors of sleep are only in a small measure coming from the external world; preeminently the disturbance arises within the organism. All its instinctive and impulsive needs which are tolerated as well as those which are repressed—the ungratified wishes, the checked tendencies, all the minuses between what was wanted and what one got, in short the whole galaxy of psychic forces which make up the living going personality in the waking state, continue to manifest themselves in the dream. Every element of its weird and grotesque structure can be accounted for by a corresponding tendency, ordinarily kept in check, breaking through the repression, weakened by sleep. Having thus attained some psychic representation in consciousness, this repressed tendency is on its way to realization. However, due to sleep, the psychomotor apparatus is out of commission. There is no way of transplating the newly emerged psychic trend into activity. Therefore the only recourse is to a hallucinatory gratification. Uncontrolled by external reality, the psychic process of the dream bears the earmarks and peculiarities of the unconscious. Among the most prominent ones may be mentioned:

1. The tendency of transposing all special sense simuli and even intellectual abstractions into visual images.

2. The peculiarity of compressing, by means of condensation, a large number of objects into one image.

3. Or the reverse, have a number of different objects express the same meaning.

4. The displacement of emphasis to secondary elements in the dream story, which adds to the obscurity of its meaning. Often the important element is indicated by a mere allusion.

In view of the fact that the imagery dealt with is essentially visual and that this imagery is to express the tendency of an impulsive striving with its active pressure for realization, the whole dream becomes subject to dramatization, and appears as a cinematographic succession.

These are some of the important data of the dream mentality one obtains, when the dream is subjected to analysis. One finds that it has a purpose and a meaning and is the expression of numerous tendencies of which the sleeper is not aware. It is because of this absence of awareness from the motive side of the dream, that it must be distinguished as having two phases. One which is given as the story of the dream—termed manifest content. The other is the psychic process behind this configuration—the latent content. The latter is the creator of the former, its psychic determinant. To get the meaning of the dream we have to decipher the manifest content, for the meaning and the purpose of the phantastic structure is in the unconscious.

We then learn that the unconscious is essentially dynamic in its nature, powerfully surcharged with affects. The affective forces take their origin from the instinctive and impulsive sources of the organism. At the very bottom of the whole mental life lie the autochthonous excitations arising from the different organs, which, reaching the upper levels of the nervous system, translate themselves into psychic excitations. It is these autochthonous excitations which constitute the impulse behind the mental phenomenon, using it and the psychomotor apparatus as a means of obtaining gratification. However, before the instinctive impulse translates itself into the highest psychic form of consciousness, it goes through the lower state of the unconscious, in which state it has all the earmarks of a psychological process, except one—namely, it is not in a position normally to influence the psychomotor apparatus. Normally it cannot determine motional activity. Its sphere of action therefore is the world of phantasy. Before it emerges into conscious, purposeful activity, it must pass the censorship of repression as to its expediency and desirability. Only after it finds a tolerable ideational content can it see the light of day. This is how the manifest content of the dream comes about. Emerging however under the condition of diminished effectiveness on the part of the censorship on account of sleep, the manifest content bears many of the earmarks of the unconscious and thus accords the opportunity to identify the unconscious. Of course we do not obtain it in its pure state, but rather as a component of a psychic structure which contains also the effects of the forces of the censorship. We can recognize it only as a part of a compromise formation. The differences between the compromise product and the normal purposeful thought processes are the qualities of the unconscious.

The twofoldness of origin of the manifest content of the dream would account for the two kinds of material that go into its makeup. On the one hand we have the rests of previous day experiences; persons one has seen and things one has done before retiring. And on the other hand the material of the dream may be made up of the most remote experiences dating as far back as the earliest childhood. The incongruity and irrelevance of the material is the mark of the unconscious. Whatever of the sequence and order of structure there is in the dream must be ascribed to the censoring function.

But be the material whatever it may—it always possesses two characteristics: It is suitable to express the unconscious tendency and it is acceptable to the then present censorship. Among the various images it uses there are some that have a constancy and consistence of connotation, not only for the individual but for the social group or even the race at large. Such an image is termed—symbol. Its chief feature is that, carrying a meaning of which the subject is unaware, it becomes adaptable to slip through the censor. It means one thing to the censor and another to the impulse which sent it out. The unconscious for this reason shows a predilection for the usage of symbols. Symbolism is one of the means of distorting the structure of the dream.

One other important fact should be mentioned, which the analysis of the dream reveals regarding the unconscious. The particular repressed craving which induces the dream is one which existed in the unconscious for a very long time. The original occasion when it sought expression and was inhibited, it was not abolished thereby—on the contrary, the fact that it was not abreacted gave it a lease of life. Its coming to the fore in the dream is an attempt to spend itself—to abreact. Now the whole unconscious content consists of such unabreacted forces which arise from all occasion of repression, but mainly from the epoch of greatest repression, namely the developmental period of early life. Since cultural development is essentially a process of inhibition of instinctive cravings, and since this takes place primarily in early childhood, it becomes clear why the unconscious bears the mark of infantility.

In connection with this note should be taken that the analysis of dreams of all persons shows that the nature of the repressed tendencies is preeminently sexual. There is no other phase of man's existence that is subjected to so many inhibitions and limitations. From the very inception of human culture every phase of human organization had as its primary objective—the regulation of the sex instinct. This problem did not diminish in extent or intensity with the advance of civilization. On the contrary, it constitutes the bulk of contemporary social regulating measures: Custom, morality, religion, family, and so forth. Furthermore, in porportion as the energy from the sex stimulation is directed to the nonsexual aim, but is harnessed for social service, culture becomes a possiblity. Every human individual must undergo all the inhibitions which the human race has evolved in the course of its cultural development. Every infant commences life with the pressure of his sex cravings as if he were born at the dawn of human society. Layer by layer of checks and inhibitions, constituting repression, are deposited to hold down the polymorphous sex instinct and to assign to it a limited socially justifiable channel of expression. The amount of energy thus spent must indeed be great, but so also must be the force of the sex impulses, which, as has been pointed out, continually persist to bombard the inclosure separating the unconscious from consciousness. It is for this reason that the unconscious as revealed by the latent dream content, is intensely colored with sex.

It is beyond the scope of this presentation to go fully into the psychology of the dream. It has been chosen merely as a means to convey the concept of the unconscious. Its features which concern us here are the following: The dream is inexplicable unless interpreted as being determined by the unconscious. The unconscious psychological processes are the derivatives of impulses which have not been abreacted. They obtain partial realization by obtruding themselves upon consciousness and make their marks upon it by distorting it. These marks are the mechanisms of condensation, displacement, identification, and other processes. The nature of gratification thus obtained by the unconscious process is that of hallucinosis. The character of its content is primarily infantile, and its dynamic force is derived from the sexual impulses.

The concept of the unconscious is subject to much attack and criticism. And yet a psychological approach to mental phenomena would be impossible without it. Symptomatic acts, dreams, hysteria, compulsions, acquire a meaning and purpose only on the basis that they are products of the unconscious. Similarily inexplicable without it would be the startling spontaneity of some complicated thought processes, which can be elaborated in astounding detail without awareness on the part of the subject. The whole problem of memory, viewed psychologically implies the existence of the unconscious since consciousness has a comparatively small scope.

Besides this consideration of the indispensability of the unconscious for purposes of orientation, we also have the direct proof of its existence in the phenomenon of posthypnotic suggestion. A posthypnotic suggestion is given to a person to carry out a certain activity. Some time after the seance the subject, oblivious of the order, spontaneously performs the required act. Between the time of being given the suggestion and the time of its carrying out, the person retained in his mind a complicated ideational system capable of translating itself into a coördinated activity, without his having a conscious knowledge of it.

Apart from being pragmatically justifiable and subject to direct proof, the status of the unconscious is as legitimate as the concept that every person other than ourselves has a consciousness. After all it is only our own consciousness which is given in immediate experience. The consciousness of the other person is always implied, on the ground that since consciousness is associated with our behavior, a similar behavior on the part of others must also be associated with consciousness. When we have before us psychic processes which possess all the earmarks of consciousness minus awareness, we are not violating the sense of plausibility when we designate them under the category of the unconscious. To classify them with consciousness would only create confusion, since they lack the characteristic feature of awareness.

From these considerations one finds himself compelled to regard all psychic processes as being first unconscious, of which only a few are appreciated in awareness. In this respect Freud compares consciousness to a sense organ. The sense organ gives an appreciation of the outside world only in some of its aspects. Similarly consciousness registers only some of the psychic events which transpire in the mind. Didactically stated—psychoanalysis conceives every psychic event as passing through two phases. In the first it is unconscious. Before it reaches the second phase it has to pass a censorship. If it succeeds it is allowed to enter the second phase, which is consciousness. If it is disapproved by the censorship it becomes repressed and must remain unconscious. In this state of being unconscious we must distinguish another peculiarity. Some of the rejected material is never able to become conscious; some other again may be admitted at certain propitious moments. This psychic material is termed the foreconscious. It is not in consciousness but it is capable of getting there.

Such an orientation in mental phenomena, with respect to the special systems it belongs to and between which it transpires, is spoken of as topical, and is characteristic of psychoanalysis.

Freud characterizes the unconscious as distinguished from consciousness by three important qualities:

1. It is devoid of the principle of contradiction; any idea may have any connotation.
2. It is timeless: Its content has no sequential arrangement as to time. Time makes no impression upon it—it does not lose its energy because of duration. In general it has no relation to time.
3. It takes no cognizance of reality. It is essentially dominated by the pleasure principle. It substitutes psychic reality for external reality.

Thus do the unconscious processes reveal themselves to the observer in neuroses and dreams. In other words dreams and neuroses represent a regression to a lower level of psychic activity.

REPRESSION.

In the foregoing consideration of the unconscious, time and again reference has been made to repression. It was implied that if a mental process is said to be unconscious that it was the equivalent to saying that it is repressed. If its state of being unconscious is comparable to a state of banishment, then repression is the function, which banishes on the other hand, and on the other keeps the excluded event in exile. It first rejects a psychic process and then continues to keep it at distance from consciousness.

What can be the immediate purpose of this exclusion? Clearly to obviate the mental pain which the event did or could engender. Whereas pain and displeasure coming from the outside world are reacted to by means of flight, upon their arising within the organism—the response is repression. To avoid pain is the immediate purpose of this reaction.

A psychic process is capable of calling forth mental pain because it tends to set off the psychomotor apparatus for bringing about gratification, which would be in conflict with the rest of consciousness. In other words, it is the impulse behind the ideational content, which is the pain producing factor. Repression is essentially directed against it.

Now the impulse clothes itself in various ideational forms. On its way towards externalization it mobilizes all sorts of ideas, provided they are suitable to carry its meaning. The various constellations thus produced are to be regarded as its derivatives. Their number is large and their configuration quite varied, but the significant thing in them is the instinctive striving, which energizes them. They are merely its representatives.

These various ideational disguises the impulse takes recourse to, in order to pass the censorship. In proportion to the removal of their ideational associations from the raw aim of the impulse, they have a better chance of passing the barrier. The main prerequisite for the evasion of the censorship of the repression on the part of an impulse is the remoteness in association of its representative ideas. Thus for example the impulse to dominate is not permitted to appear raw and naked, by the higher consciousness of the cultured man. But when, however, by way of association of ideas it emerges as a patriotic motive, or as an aim of social service, then it is granted admission and is reckoned with as a laudable quality of the statesmen. Another example is that of the sex urge in a young girl. It is utterly tabooed by her ego unless it manifest itself under the disguise of friendship, desire to assist or redeem, interest in intellectual and moral qualities. All these derivatives evade repression because of their remoteness from their source.

Between the raw aim of the impulse and its much disguised form, there are numerous energized ideational systems, all of which are kept below the threshold of awareness. Their being repressed does not in any way affect their viability. Repression only determines as to what system they are to belong to. In the unconscious they continue their existence. There they are capable of all kinds of combinations amongst themselves. An extreme example of such ideational combinations is the phenomenon of double personality.

Interesting is the fate of the impulse and its derivatives with respect to the degree of repression applied to them. The more complete the repression, that is, the fewer and narrower the channels for their collateral discharge, the more effective is their influence upon the rest of the content of unconsciousness.

Proportionate to the amount of their pent up energy, they weave and combine with all sorts of elements, of most remote associations. They thus evolve a structure which upon a sudden or chance uncovering of the unconscious, astounds one as to its magnitude and complexity. Clearly their power is derivable from the fact that as a result of their being repressed, they were not accorded gratification; they were not abreacted. Their energy is utilized by way of an unchecked development in phantasy.

The remoteness of association as a criterion for the evasion of repressions is made use of in psychoanalytical technic. In the course of analysis the analyst has repeated occasion to observe that the patient would suddenly halt in his work of association, let us say, for a dream element. As the associated ideas approach closer to the tabooed impulse derivative, the stream of thought becomes hesitant, intervals of absence of ideas become longer, and finally the whole train of ideas comes to a standstill. Clearly one is in proximity to some impediment or barrier. Upon overcoming this difficulty by means of insight or explanation, the patient is able to continue with the association. After several such halts—one finally penetrates the obstruction and gets at the sought for impulse. This work entails a most laborious and devious route to reach the aim. The way thus followed is the one which repression has laid. It varies greatly for different patients. Some required but little distortion, others again were in need of a profound and extensive disguise of their original striving. These difficulties and halts in the work of association are termed resistance, which is clearly a form of repression.

Repression and resistance are different names for the same force; they indicate merely the direction in which the force works. Repression prevents the impulse from reaching the light of day. Resistance prevents the light of day from reaching the impulse. The phenomenon of repression accords one an insight into the composite nature of an ideational representative of an impulse. In it one must distinguish the idea and the energy derived from the impulse. The latter is termed the affect quantity, because when it is separated from the former it usually registers itself as an affect. Thus for example, the affects of anger and fear manifest themselves mainly in proportion as the situation calling them forth does not permit a response in orderly thought or action. The nonharnessing of the impulse energy by means of an idea or a psychomotor activity results in the affect.

There is a considerable difference in the destiny of these two elements, when a psychic process is subjected to repression. The ideational content on being excluded from consciousness ceases thereby to manifest itself, and is thus disposed of. But the quantitative factor—the energy—may be taken care of or distributed in one of three ways. 1. Either it is completely repressed and is rejected to the unconscious, or 2. It appears as some affect, or 3. It manifests itself as unmotivated anxiety.

Since the purpose of repression is to obviate pain and displeasure, it is clear that when there results an unpleasant affect or anxiety that the repression has been unsuccessful, even though the ideational content has been disposed of from consciousness. The hysterical anxiety or the hysterical spell are examples of an unsuccessful repression, in which the affective quantity contiues to manifest itself, despite the fact that the ideational content has been eradicated. There are several, perhaps many ways by which repression may operate; but they all have one feature in common, namely—the separation of the ideational content from the energy factor. Since oblivion is the fate of the ideational content, the whole problem which repression engenders is what is to become of the affect quantity? The modes of disposal of this factor are spoken of as the mechanisms of repression.

We shall illustrate some of them. The mechanism of displacement is a common form in which repression operates in the production of an hysterical phobia. The analysis of the clinical syndrome of an animal phobia reveals the following: A libidinous striving to the father is repressed. The idea father is banished. The emotional quantity changes into anxiety. The idea father is substituted for by a mental presentation of an animal. Hence the hysterical fear of the animal. The symptoms constituting the phobia are a reaction to this fear.

Another mechanism of disposal of the energy quantity is that of conversion—as in conversion hysteria. One of the chief characteristics of a pronounced case of this type is the absence of affect, a remarkable complacency, which Charcot termed *la belle indifferencе des hysteriques.* Here the substitute which takes on the energy change is an organ or a limb, which attracts onto itself and thus localizes the affect. It condenses in itself the various aspects of the repressed psychic process.

The repression in a conversion hysteric with regard to its disposal of the affect is more efficient than in anxiety hysteria, but as regards the fact that it has to maintain a permanent and extensive substitute it is a failure.

Another important mechanism of repression is that of reaction formation. This is best observed in a compulsion neurotic. The predominant feature of such a patient is the ambivalence of his feelings. Hate and love with regard to some object coexist readily in him. Ordinarily one phase of the ambivalent attitude is repressed in early childhood, so that normally there emerges a homogenous feeling attitude. The child displays only the affectionate side of his attachment. The energy of the repressed phase of the striving is withdrawn. The opposite ideational content is chosen and a substitution is thus formed—termed reaction formation.

In the child this reaction formation will manifest itself as overzealousness to please, and later in over conscientiousness to its school work, habits of dress and hygiene, and so forth. Part of the energy of the repressed phase obviously is thus being utilized for the building up of the ego.

This arrangement however may break down in later life. The original repressed ideational content may again become energized and to the fore would come the tabooed phase of the original impulse, giving rise to the primary symptoms of the compulsion neurosis—the sadistic striving.

This new situation would again call for the work of repression, for a second removal of the affective energy and its displacement onto ideational systems of an opposite character to the sadistic urge. The symptoms of social anxiety, conscience fear, self reproaches, and other symptoms, carry on this work. The rejected ideational system against which these efforts are directed is replaced by some insignificant or indifferent matter or object. Hence the incongruity and irrelevance of all these efforts. Reaction formation and displacement are the characteristic mechanisms by which repression manifests itself in compulsion neurosis.

These remarks on repression based upon Freud's original contribution to the subject, aimed to convey an idea of the nature purpose and mode of operation of this important function and the insight one gains through it into the dynamic character of psychic processes. One thing is certain that an appreciation of its significance is indispensable for the understanding of the unconscious. In fact, the concept of repression is a corollary of the concept of the unconscious.[1]

A Preliminary Report on Observations on Localized Iris Changes

By SAMUEL P. SOBEL, M.D.,
New York.

For the past four months I have been making an experimental and clinical study of iris changes in disease and trauma. I observed in numerous operations on the dog a localized movement within a definite area of the iris, the area of motion depending upon the organ operated on. The area involved was either triangular or circular, sometimes irregular in shape. The rate of motion varied from one to three times a minute. Many of these experimental operations were performed repeatedly, and the area of motion was always identical, though rate of motion varied somewhat in the different animals.

In humans, motion was also visible, and also repeatedly seen in the same area in the same type of operation. Sometimes no movements were seen, but the formation of new lines in the iris was noticed during the operation. The area in which the motion appeared took on a different appearance after the operation. This always remained permanent, as did the new lines formed.

In disease, discolorations appeared in definite areas, also depending upon site of disease process. These changes will be described in detail after further observation.

Histological studies of the iris show, so far, a redistribution of the iris fibres. Studies for the purpose of determining whether pigment changes occur are also being made.

As I am now in a position to take photographs of the iris, I hope to be able to present with my next report photographic proofs of these iris changes.

Report of a Case of Belladonna Poisoning by Topical Application

By HERMAN FRIED, M.D.,
New York.

As cases of belladonna poisoning by local application are unusually rare and as I have recently encountered one in private practice, I present it as a contribution to the somewhat meagre literature of a subject of general interest to the medical profession.

CASE.—Mrs. A., a Turkish Jewess, twenty-eight years old, came to my office, February 2, 1922, for consultation and relief. She complained of jerky pains in the lumbar region. She described it as a stitchlike pain which the slightest movement made unbearable. Any change of position brought forth severe pain. The muscles of her back I found to be tender on pressure. She gave a history of a similar attack two years previously. As there was otherwise nothing apparently abnormal in her condition, I diagnosed the case as myalgia lumbalis and advised applications of heat with hot water bags or electric pads. I also prescribed as a liniment: Tincture of aconite, two drams; tincture of belladonna, four drams; spirit of chloroform, four drams; add sufficient soap liniment to make six ounces. This is to be applied by gently massaging or rubbing the muscles of the back.

About twenty-four hours later I was called to see the patient at her home. I found her in bed, restless, giddy, very talkative, complaining constantly of pain in her throat and persistently trying to get out of bed. Her face was flushed, eyes bright, pupils dilated, tongue coated and dry, fauces and uvula reddened. Her chest was covered with a patchy erythematous rash. Pulse and respiration were markedly accelerated. Rectal temperature was 101° F. At times she was delirious.

Inquiry among the members of her family brought out the information that the liniment had been continually applied to her back until the entire amount called for in the prescription had been consumed. Further investigation established the facts that ordinarily she did not use drugs of any sort and that she had not taken any of the liniment internally. Used externally the whole amount of four drams of belladonna would seem to have been wholly inadequate to produce the severe toxic symptoms that the case then presented. It seemed hardly possible that I could be dealing with a case of belladonna poisoning by local application, and yet the symptoms, taken separately or collectively, pointed unmistakably and exclusively to that diagnosis.

My first thought was morphine as physiological antidote to atropine; but in this case I soon found myself in error. I therefore administered other antidotes both chemical and physiological. Six drops of Lugol's solution hourly and a quarter of a grain of pilocarpine hydrochloride were effective. Close surveillance was kept over the patient for a period of forty-eight hours, by which time her recovery was complete.

It is probable that the mechanical friction of the rubbing contributed materially, as well as the camphor, chloroform and alcohol of the liniment mixture, to the easy absorption of the belladonna by the skin; but some condition of individual idiosyncrasy also must be held, in this case as in some of the others, to account for the unusual severity of the symptoms as well as for the failure of the expected effect of the morphine.

Of the other three cases recorded in the literature of belladonna poisoning by local application the most recent is that of R. K. Ketkar (1). The patient, a man, thirty-five years old, an outpatient, came for swelling and pain of two days' duration in the right side of the scrotum. There was no history of venereal disease, but there was a history of a similar enlargement two or three times several years before. His temperature was slightly above normal; bowels constipated; urine normal. Diagnosis was made of acute orchitis, probably caused by slight local trauma. Epsom salts were given immediately and a diaphoretic mixture three times a day. Tincture of iodine was painted locally and a light scrotal support was employed. The patient returned the same night, complaining of a rather heavy, dragging, unbearable pain in the scrotum. This time glycerine belladonna was applied, and the part properly bandaged.

Next morning about eight o'clock, the patient's tongue had a greenish blue coating; he felt dryness in the mouth and had nausea. He felt drowsy and giddy, his face was flushed, pupils were dilated and feebly reactive to light, and an erythematous rash covered his cheeks, especially marked around the eyes and over the malar bones. He complained of restlessness and thirst, vertigo and staggering, and a desire but inability to micturate and defecate.

The patient's scrotum was immediately cleaned free of all the paints and applications with soap and water, he was given a simple suspensory bandage, and, internally, a diaphoretic and diuretic saline dose. Later, as the bowels did not act and the restlessness persisted, a soapwater enema was employed, followed by an emetic draught of zinc sulphate. The patient was much relieved and frequent draughts of effervescent soda water were all that were then required. The scrotal trouble disappeared altogether by the next day.

Ketkar's conclusions from his case were that the iodine, possibly with a certain amount of scratching, perhaps unknowingly some of the applications introduced into the mouth, and certainly some personal idiosyncrasy were responsible for the toxic effects.

B. G. R. Crawford reports a case (2) of a strongly built, muscular laborer aged thirty-seven. He was seen first at 11 a. m., when he complained of pain in the back. Nothing abnormal as to pulse and temperature was discovered, and, as he was anxious to return to work, a belladonna plaster six by four and a half inches was applied.

At 2 p. m. he was carried in on a stretcher, struggling and held by two men. The skin was harsh, dry and reddened, pupils dilated, pulse 130, respiration 40; he was semiconscious and delirious; his temperature was unobtainable on account of his movements. The plaster was immediately removed and he was admitted to the hospital.

At the hospital he remained in the same condition until 9 p. m., when he quited down and sank into an uneasy sleep. His pulse then was 115, respiration 30, temperature 97.5°. The next morning he was much better, though the tongue and lips were dry and furred and he was still slightly incoherent in speech. He had no recollection of what had occurred. Two days later the only remaining sign was slightly enlarged pupils responding slowly to accommodation. Pulse, respiration and skin condition were normal.

Crawford considered the symtoms to be due directly to an overdose of atropine absorbed from the plaster through the skin in a susceptible subject.

The third authentic case was published by Dr. Allen Starr (3) as having occurred in his practice some ten years before. It differs somewhat from the others in the effect of the poison on the personal idiosyncrasy of the patient, which was in his case mental rather than physiological.

The patient was a young man brought by his brother and suffering from great nervous excitement and exaltation with delusions of wealth and power wholly outside of and beyond any of his experiences and circumstances. The attack had been sudden and greatly alarmed the brother who feared the patient must be immediately confined in an asylum.

The available information was to the effect that the patient had had a severe attack of lumbago the week before, and that a druggist whom he had consulted had recommended plasters. Two large plasters marked belladonna covered his back. He had no physical signs of general paresis. His pupils were widely dilated, but he had no dryness of the throat and no eruption on the skin.

The plasters were removed at once, a long Turkish bath was taken and bromide was prescribed. In forty-eight hours his brother brought him back mentally nearly normal and two days later he was able to return to his ordinary occupation in perfect health. Dr. Starr's conclusions were, as reported, that the sudden development of illusions, delusions, and hallucinations should always arouse a suspicion of toxic psychosis.

In considering and comparing these four cases, the first point to be noted is that the toxic effect of the poison was produced in every case by absorption of the poison through the unbroken skin. Cases of belladonna poisoning are not uncommon, but the port of entry will be found to be usually by way of mouth or of some abrasion or ulceration of the skin; the second is that, although commercially standardized doses only were administered, which under ordinary circumstances do not unfavorably affect most persons, they have entirely different and dissimilar effects upon other persons; the third is that this effect must be attributed to some peculiarity, physical or mental, in the constitution of the person so affected; and fourth that these peculiarities, susceptibilities and idiosyncrasies must be guarded against, if the physician would not invite disaster.

In my own practice, as in that of every medical practitioner, these idiosyncrasies are a source of constant surprise. Alarming symptoms of toxemia and urticaria are often manifested, as in one case following ingestion of blackberries or strawberries. In another after a ten minim dose of turpentine administered in a typhoid faver case, my patient showed marked signs of intoxication, exhilaration, giddiness and urinary irritation. In another case of hereditary syphilis, after an ordinary external application of white precipitate ointment, the patient suffered from nausea, vomiting, bloody diarrhea and collapse, and erysipelatous dermatitis. Often indeed the eruptions are caused by drugs mistaken for some serious skin disturbance. These unhappily cannot always be foreseen.

CONCLUSIONS.

My conclusions from this case and a study of the toxicology of belladonna generally and specifically may be stated as follows:

1. Careful investigation of the personal and family history should be instituted to discover and counteract idiosyncrasy.

2. Morphine should be used with extreme caution, or not used at all.

3. The patient should be kept under uninterrupted supervision; being usually in a state of delirium, injury to himself or others must be guarded against.

4. The treatment should begin with stomach evacuation with a tube or by means of emetics.

5. The best chemical antidote for belladonna poisoning is Lugol's solution in doses of six drops, the frequency being conditioned on the amount of the poison absorbed.

6. Tannic acid in twenty grain doses is an admirable substitute, should Lugol's solution not be available.

7. Pilocarpine hydrochloride may be administered hypodermically in quarter grain doses as physiologically antagonistic to atropine.

8. Supportive treatment with strychnine, caffeine and brandy should be instituted if the pulse becomes weak and respiratory failure imminent.

Chronic Ulcerative Colitis and Its Treatment*

By MAX EINHORN, M.D.,
New York,
Visiting Physician to the Lenox Hill Hospital, New York.

Chronic ulcerative colitis has been the subject of much discussion recently. H. Strauss (1) has analyzed this affection in his monograph, *The Sequelæ of Dysentery,* in great detail. He considers many of these cases as the result of dysentery, even if there is no direct proof of this disease at the time the patient presents himself for treatment.

Yeomans (2) has recently published an important paper on chronic ulcerative colitis of indefinite etiology embracing sixty-five cases of his own. Yeomans believes that we have to deal here with an infection causing the inflammatory process. This view is favored by the fever present at the beginning of the disease, the great prostration which occasionally appears during the sickness, and the septic processes (such as arthritis) complicating this affection in its late stages.

Chronic ulcerative colitis is of frequent occurrence and deserves a thorough discussion on account of its frequent relapses and its great resistance to many modes of treatment. The disease process consists, as indicated by the name, in an inflammation of the colon with ulcerations. The latter are encountered in the various parts of the large bowel, but principally in the lower portion of the descending colon.

SYMPTOMS.

The symptoms most frequently found are: numerous watery, mucous evacuations, occasionally with an admixture of blood; rumbling in the abdomen; at times tenesmus; poor appetite; loss of weight; general weakness, and disturbed sleep. Occasionally there appear remissions in the disease process during which the patients suffer less; rarely, however, is there a normal evacuation, although there exists a diminution of diarrheic stools and at times also a better formation of the evacuation. At times again, there are exacerbations of the symptoms, when the stools are watery and bloody and there exists great prostration accompanied occasionally by fever. During such a period the tenesmus is usually present. The disease drags along for many years, during which time the patients are frequently unable to work and are occasionally bedridden.

DIAGNOSIS.

The diagnosis of chronic ulcerative colitis is generally not difficult. Occasionally the history of the case, if it is typical, makes it possible to recognize the disease. Thus, symptoms of intestinal discomfort, frequent diarrhea with mucous and bloody admixtures in the stools, occasional tenesmus, and abdominal colicky pains, justify the diagnosis of chronic ulcerative colitis, provided there is no pulmonary tuberculosis present. Often the symptoms are not sufficiently typical, and the new means of examination can be utilized in order to establish the diagnosis. They are, as everybody well knows, the examination of the rectum with the proctoscope, which shows the inflammation of the mucosa and occasionally small defects of lentil size or a trifle larger, situated in the rectum or sigmoid, and the x ray examination of the colon after a barium enema. By this means in advanced cases contraction of the lumen of the bowel and no haustration of the colon are found.

If the ulcers are situated high up in the colon the proctoscope will of course fail to show them. The examination of the stool, however, will always reveal the presence of blood and pus corpuscles. The prognosis must be guarded on account of the great obstinacy and persistence of the symptoms and also on account of the numerous possible complications.

TREATMENT.

The treatment comprises dietetic, medicinal and mechanical measures. The diet consists in arranging for a sufficient amount of nonirritating foods,

---

*Read before the Association of Karlsbad Physicians at Karlsbad, Czechoslovakia, September, 1922.

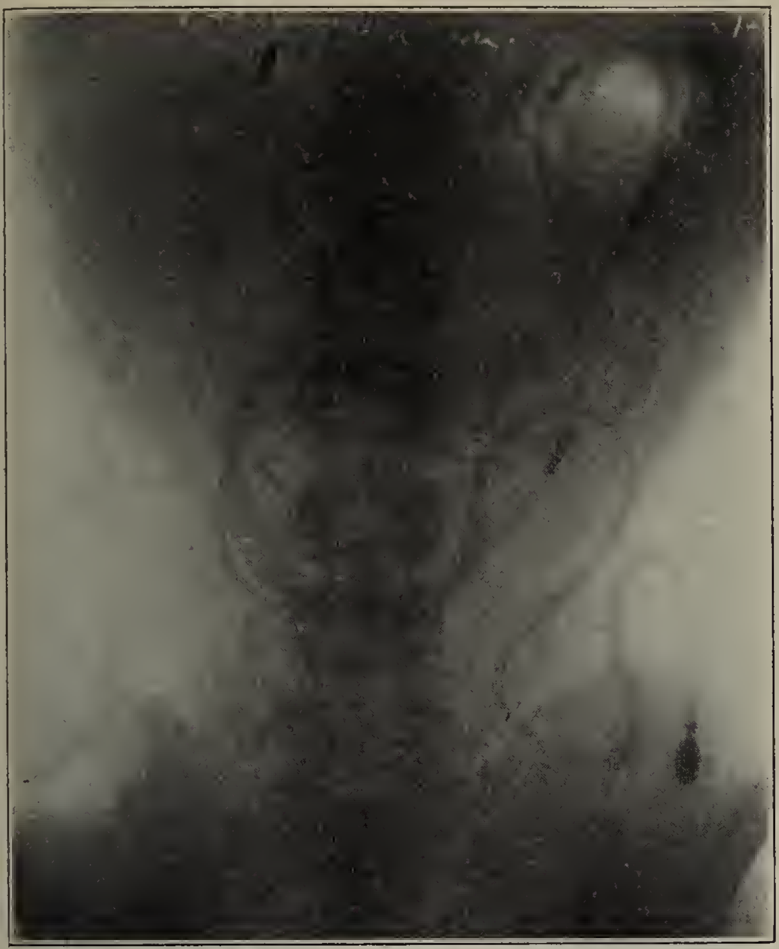

Fig. 1.—January 26, 1922. X ray of abdomen of J. F. The end of the intestinal tube is seen in the small intestine. There is also noticeable a curling up of the intestinal tube in the stomach.

containing very little cellulose matter. Eggs, raw or soft boiled, gruels, tender meat, wheat bread and butter, potatoes (baked or pureéd), tea, cocoa, blueberries, and acorn cocoa, best serve the purpose. Cold beverages, fruits ,and salads should be avoided.

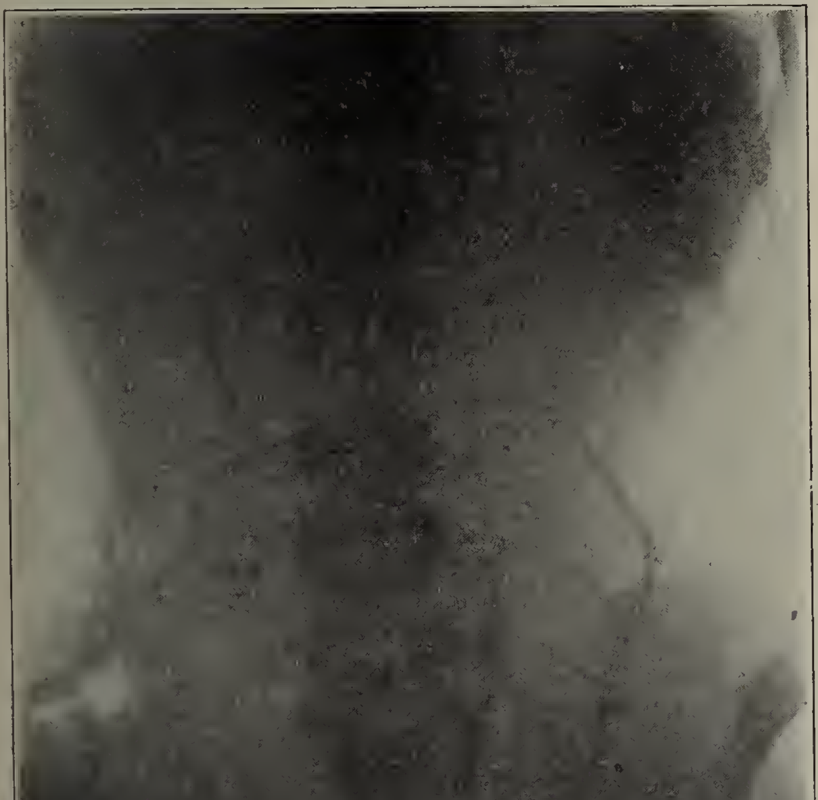

Fig. 2.—January 29, 1922. Same as Fig. 1. The end of the intestinal tube is visible in the latter part of the ileum. There is no curling of the tube in the stomach.

Milk is generally not well borne by these patients. Small quantities may, however, be given a trial, when used as an addition to other foods. After meals the patient should rest one half to one hour. If the patient is improving, vegetables are added to the bill of fare given above.

No matter what kind of a diet is given, it is always necessary to look out for a sufficient amount of nutriment. During an exacerbation of the illness this will, for a certain time, be hardly possible, but in almost every case one soon succeeds in achieving this object. In the general plan of the dietetic régime for any length of time, the principle of sufficient nutrition comes first, and the question of what kind of foods second.

For short periods of time, however, it is possible to apply a scanty (insufficient) rest diet, provided there is some prospect of accomplishing a more rapid recovery (or amelioration) by this socalled rest cure for the intestine. After completing the period of rest one returns quickly to an increased sufficient diet. Frequently the patients are undernourished, and it is necessary to arrange a diet, which would increase the body weight. This can be easily accomplished by instituting frequent meals and giving a good deal of butter. An increase in weight strengthens the whole organism, which is thus enabled to fight the disease more vigorously.

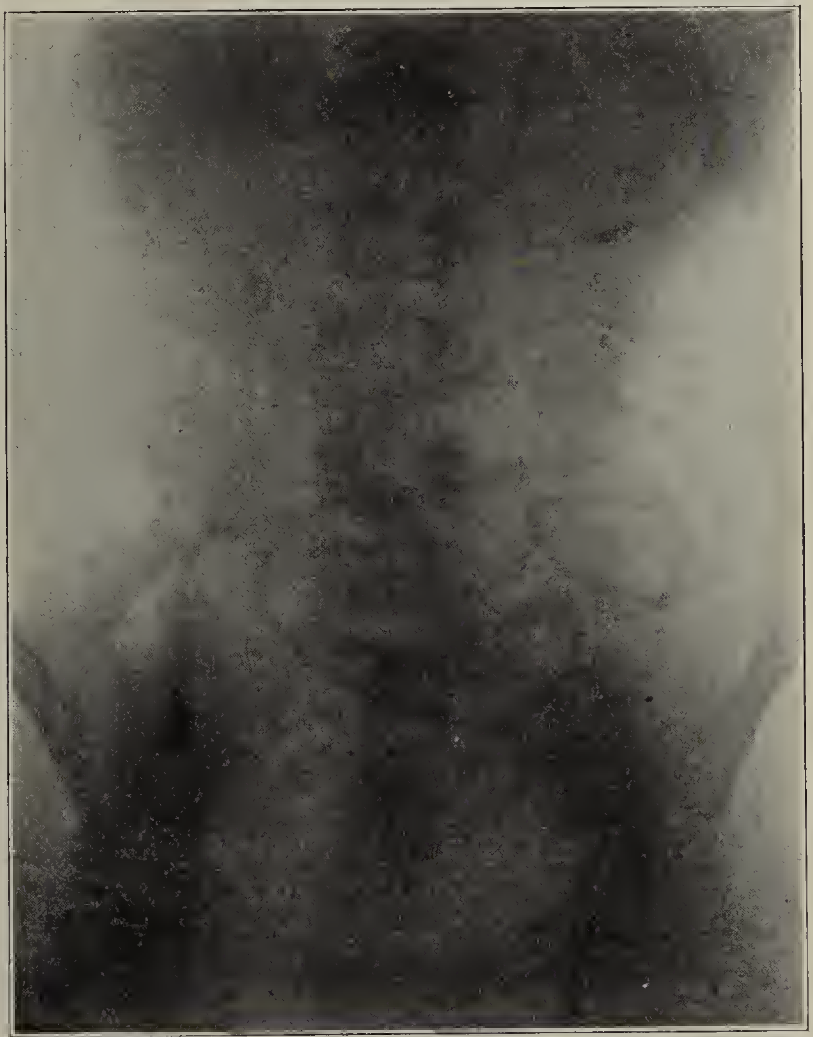

Fig. 3.—January 30, 1922. Same as Fig 1. The end of the intestinal tube is visible in the cecum. The tube shows the course of the entire small intestine.

The medicinal treatment consists, as is well known, in the administration of astringents and absorbents, as well as opiates. While these medicaments are occasionally of use, they prove of no value in many of the severe cases.

In a similar manner, as Schmidt applied agar in conjunction with cascara sagrada for the treatment of constipation, I (3) have used the same vehicle containing astringents in order to combat diarrheas.

The advantage of the medicated agar in the treatment of intestinal affections consists first in having the remedy spread over long portions of the intestine, for the medicament contained in the agar escapes but slowly by osmosis during its forward movement through the digestive tract. Secondly, the agar prevents the fecal matter from becoming too dry, which occasionally happens when astrigents are given, and which leads to renewed irritation of the intestinal mucous membrane.

Practical experience with agar preparations, such as, tannin agar, simaruba agar, gambir agar and myrtill agar, have proved their value in combating ulcerative colitis. One to two teaspoonfuls of these preparations may be given three times daily after meals in water. Whenever there is a possibility of the ulcerative colitis having taken its origin after an attack of amebic dysentery, a combination of the agar astringents with ipecacuanha agar is very useful. In the presence of severe colicky pains lupulin agar is best added to the medicaments mentioned above.

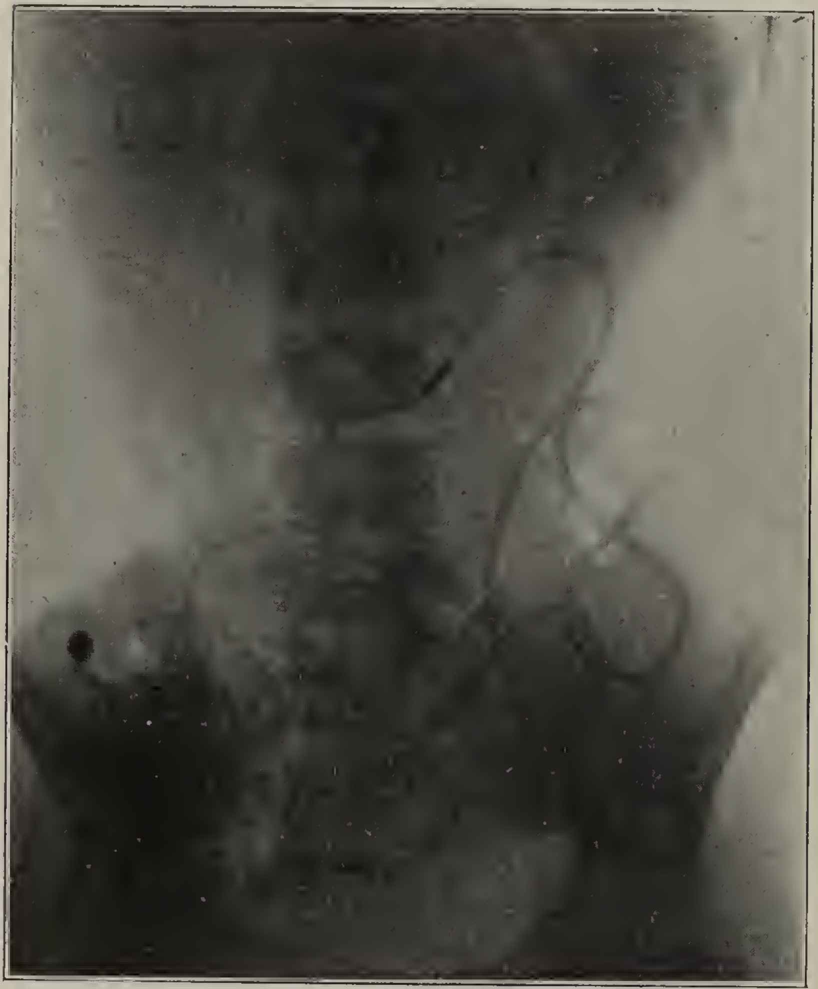

Fig. 4.—February 1, 1922. Same as Fig. 1. The end of the tube is situated in the cecum in a position slightly moving upward along the ascending colon.

I can warmly recommend these agar preparations and would like to say, that since using them I hardly ever find it necessary to prescribe opiates in severe diarrhea, as it is possible to master the situation without them.

LOCAL TREATMENT BY MEANS OF RETENTION ENEMA AND IRRIGATIONS THROUGH THE RECTUM.

For the retention enemas, which may be given in quantities of 150 to 250 c. c., the following media have proved of value; gelatin enemas of ten per cent., alone, or with the addition of adrenalin ten

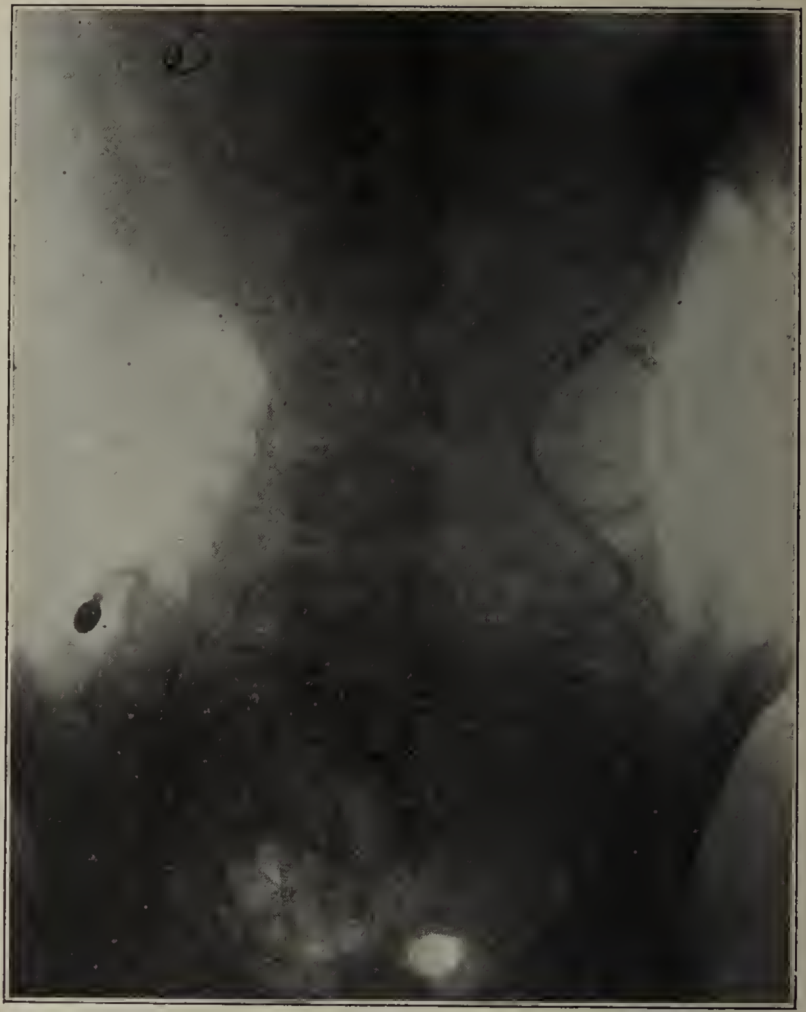

Fig. 5.—February 6, 1922. Same as Fig. 1. After inflating the colon with oxygen gas through the intestinal tube. The ascending colon is nicely filled out by the oxygen gas, pressing the capsule end of the tube downward. The haustræ of the ascending colon are likewise clearly shown.

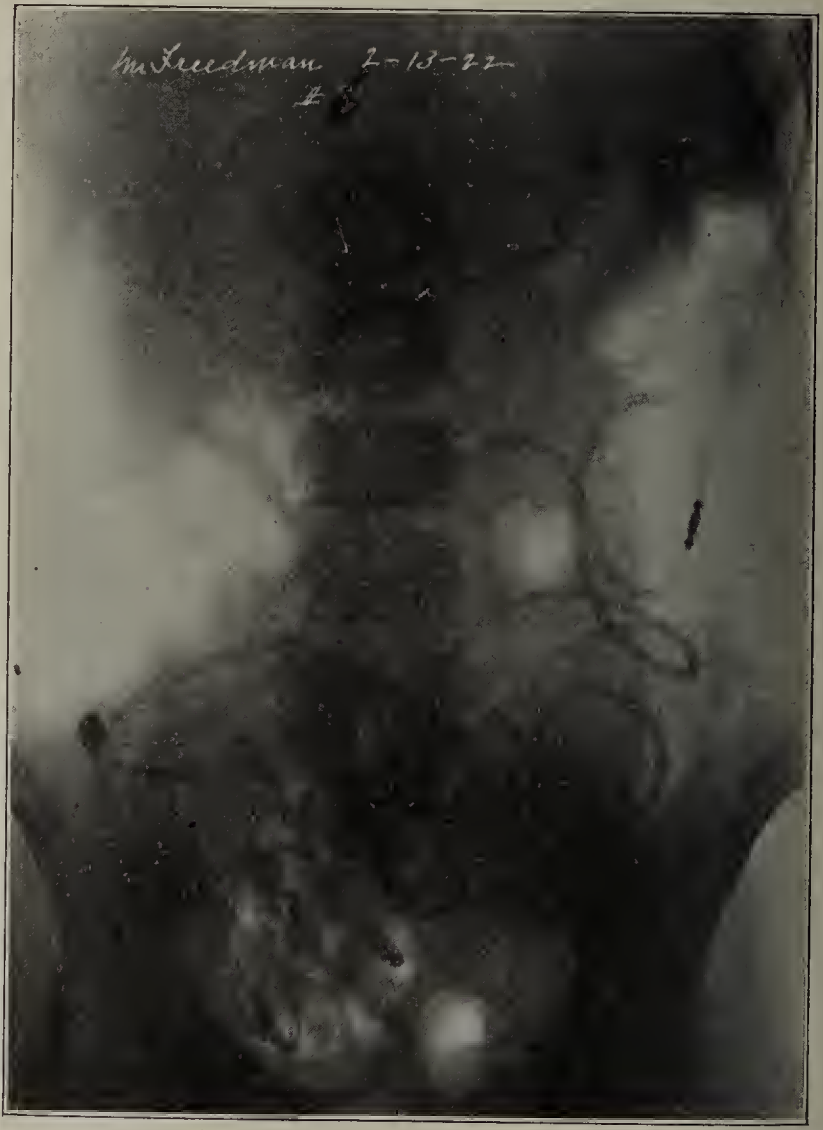

Fig. 6.—February 13, 1922. Same as Fig. 5. A week later, after oxygen inflation. The end of the tube visible in the cecum.

to fifteen drops of the 1:1000 solution); fresh blueberry juice or myrtill extract and water, equal parts, with the addition of a teaspoonful of powdered starch; also bismuth emulsion (subcarbonate of bismuth 25.0; aq. distil., 200.0, mucilage of acacia q. s.) can be advantageously used for this purpose. After a preliminary cleansing of the colon, these small enemas are slowly instilled, at blood temperature, into the rectum and the patient instructed to retain them as long as possible.

For irrigations of the colon through the rectum one may employ weak solutions of argyrol or of tannic acid, camomile decoctions, physiological saline solution, tap water with essence of peppermint (one teaspoonful to a quart), or a one half of one per cent. solution of ichthyol. In the presence of much mucus in the stools irrigations with warm Carlsbad Sprudel water can be given.

In severe cases of ulcerative colitis the surgeons recommend the establishment of an appendicostomy or cecostomy, in order to flush the colon from above, through the newly established opening. This procedure proves in many instances more efficacious than simple irrigations through the rectum.

During the last two or three years I have attempted to avoid this operation by introducing an intestinal tube through the mouth into the cecum. When the tube has reached the latter organ, irrigations can be established through the former, flushing the colon from above downward, as through the appendicostomy opening. The tube is left in place for two or three weeks and is used merely for purposes of treatment, while the nutrition of the patient takes place by mouth in the usual way.

The reports of two cases of ulcerative colitis successfully treated by this method have been published by me not long ago (4 and 5), and I now report another case of this affection, in which the method of treatment, outlined above, was applied.

CASE I.—January 20, 1922, J. F., twenty-three years old, gave the following history: In 1918 the patient was troubled with diarrhea and passed considerable amounts of mucus in the stools. In 1919 he passed some blood. He was treated and relieved of his symptoms for a time, until in September, 1921, he began having bloody stools. Local treatment through a proctoscope brought considerable relief. There was no pain. At this date the bowels moved three or four times a day, blood following the stools which were expelled with considerable effort.

The patient's previous history showed that he had had influenza in 1918, followed by rheumatism. There was no chancre; Wassermann was negative in 1921, his habits were good. He had eaten a general diet until six months ago. The patient lived in Connecticut. Physical examination showed a fairly well nourished man; with a muddy skin and acnelike eruptions over face and chest. Mouth and chest were negative; abdomen, liver, and spleen were not enlarged; cervical and inguinal glands were palpable; urine was negative; blood: hemoglobin, eighty per cent.; red blood cells, 4,000,000; white blood cells, 7,900; polynuclears, seventy-one per cent.; small lymphocytes, twenty-four per cent.; large lymphocytes, four per cent.; transitionals, one per cent.

The duodenal bucket examination was negative; i. e., there was bile below twenty-four inches and no blood stains on the string. The gastric contents revealed hydrochloric acid plus; acidity, 50. Patient complained continuously of slight colicky pains in the abdomen, frequent diarrhea and tenesmus. Examination of the stool showed much mucus, pus corpuscles, and red blood cells; no amebæ or ova of parasites. The proctoscopic examination revealed congestion and reddening of the rectal mucosa and small lentil sized exfoliations of the mucosa, extending toward the sigmoid flexure.

The patient was not improving under the ordinary methods of treatment and I decided to institute flushing the bowel from above by means of the intestinal tube. For this purpose the first joint of the intestinal tube was introduced into the digestive tract on January 23, 1922. On January 24th, the second joint was screwed on and when the latter passed in, instillations of a weak calcium carbonate solution 0.5:1,000) were begun by the drip method through the tube. On January 25th, the third joint of the tube was introduced and on the 29th, the capsule piece of the tube was lodged in the cecum. From then on daily instillations of 100 c. c. of one half of one per cent. mercurochrome solution were added to the flushings of the colon with the calcium carbonate solution, through the tube. This treatment was pursued without interruption up to February 13th. As mentioned above the patient took his nourishment in the usual way by mouth without experiencing any inconvenience from the long tube.

From time to time x ray pictures of the patient were taken, in order to ascertain the position of the tube. From January 29th, to February 13th, the end piece of the tube was always in the cecum, as can be seen from the x ray photographs. Several times insufflation of the colon with oxygen were performed by the tube. Fig. 5 shows patient after filling the large bowel with oxygen gas. The position of the end of the tube (capsule end) in the cecum can now after filling the colon be recognized with greater accuracy.

On February 8th, an attempt was made to perform a direct flushing of the large bowel from above, after a previous cleansing of the colon from fecal masses and after the introduction of a large size rectal tube into the anus. This was successfully done. One could see that the fluid running in from above through the intestinal tube into the cecum appeared directly through the rectal tube, in such a way that a direct continuous irrigation of the entire colon was established. This was repeated several times with the same good result.

During the tube treatment, and notwithstanding that the intestinal sympoms showed a decided improvement, the patient was seized with an attack of acute rheumatism with high fever. The colon irrigations from above and the diet by mouth could, however, go on uninterruptedly during the entire period of fever, without any inconvenience to patient. On February 10th, the patient was free from fever, had no more pain in the joints, and he felt much better also with regard to his intestinal symptoms. He had two evacuations daily with no blood in them.

On February 13th, the distal joint of the intestinal tube was pulled forward, unscrewed and removed.

This was done with slight resistance but no pain to patient. On February 14th, the rest of the tube was withdrawn by the mouth. The intestinal tube had been in the digestive tract of this patient for about three weeks, and the colon irrigations through the cecum had been performed for fourteen days. The patient showed decided improvement.

As in the former two cases, this case shows that the appendicostomy or cecostomy operation for the purpose of bowel irrigations can be obviated by the intestinal tube, which certainly signifies a great advantage for the patient.

The Rôle of Focal Infection in Disease

By SYDNEY PERN, F.A.C.S., L.R.C.P., Lond.,
Melbourne, Victoria.

At the present time one of the profoundest advancements in medicine is occurring. This is destined to play a part rivalling that brought about by the work of Lister. The condition referred to is the rôle of focal infections. Although much work has been done in this direction, the extent to which such infections are responsible for damage to man is not fully grasped.

Going back into the times when life began and considering the possibilities of damage to cell life in those times, we come to the following conclusions. That outside of the invasion of one living organism by another, for purposes of protection, habitation, or nourishment, there was little that could hurt a multicellular animal. In certain cases the invasion may be advantageous to the host. It has recently been suggested that the Bacillus coli is alone capable of splitting up tryptophan into indol and skatol, thereby making the indol available to combine with the iodine to form Kendal's thyroxin. But the majority of cases show detriment to the host. The only other harmful conditions are extremes of temperature and light, lack or excess of water, deficiencies of the necessaries of life, absorption of some toxic element, and, possibly, electrical phenomena. Are these conditions in any way altered at the present day? It does not appear so.

There are many diseases of unknown causation assailing the human body. All disease is either hypofunction or hyperfunction of body tissue; hypofunction being due to destruction, hyperfunction to irritation. If the effects of temperature, dryness, deficiencies, and toxic elements are excluded we have to fall back upon the presence of an invading organism as the most common cause of damage to cell life. The human being is infested with bacteria. Because it is so, does not necessarily mean that it is natural. They may be on the surface or in the body cavities and as such may be harmless unless they gain access to the body proper. In many cases these invaders are harmless, in many detrimental to existence. At first appearance it seems too overwhelming a problem to rid our bodies of these unwelcome invaders. It is generally recognized that man's span of life and usefulness is invariably cut short by gradual deterioration of his tissues, brought about by the presence of toxins, either of bacterial origin or indirectly, formed by faulty metabolism. If these could be eliminated man would live to old age unimpaired in faculties and vigor. Can this Golden Age be arrived at? If not, what can be done to help it on the way?

Bacteria have different ways of attacking the body and the body has different ways of defending itself against them. Invading organisms may be roughly divided into three groups. Those that invade the body, multiply freely, and are either wiped out or destroy the host. Measles is an example. These often give lasting immunity. Those that live and multiply within the body proper and gradually destroy the host or are slowly eliminated, as, for example, the bacteria of syphilis and tuberculosis. Those that live and multiply in close contact with the body or in sheltered areas from whence they can poison the body with toxins, gain direct entrance and are destroyed. The latter do not multiply indiscriminately within the body, except where they are able to set up another sheltered barrier. These by their constant invasion so reduce the defense mechanisms that they do great damage before they are killed off. If they were not killed or eliminated they would of necessity multiply and overwhelm the host. Such an instance is seen in the supervention of miliary tubercle on a long standing case of phthisis.

Mobilization of the defensive forces in many cases gives the first indication of disease. In other cases there is direct cell spoiling of highly specialized tissues without signs of mobilization. Hence hyperfunction and hypofunction of tissues constitute disease.

As stated the majority of bacterial invasions are wiped out and there is an end of them, with the result that the body is soon able to repair the damage done, and is as good as ever.

It is to the other type mentioned where bacteria live and multiply in a safe retreat year after year that our attention is seriously drawn. These bacteria are constantly pouring toxins into the system, sending raiding forces into the blood and lymphatic streams whose bactericidal powers are steadily reduced by constant invasion. They are attracted to tissues for which they have a selective affinity. On being met by resistive forces they eventually succumb. Infection of this nature is sapping the vitality and destroying the tissues of the majority of men. What are these infections? Where are they? What organisms are responsible?

The infections we now call focal infections. So much has been written about them that it is needless to dwell further upon their designation. Their localization is also known. The organisms responsible vary, the species does not matter so much; it is the method of operating that counts. Of them all perhaps the streptococcus group stands out supreme. From the work of Rosenow and others one must conclude that many forms are the same organism at different stages of transmutability.

It is a commonly accepted fact that streptococci and other organisms may be found almost universally in the mouth and tonsils.

In these locations the organisms are outside of the body proper and may be more or less harmless. We know that the digestive powers of the stomach are capable of dealing with most organisms that are swallowed; we also know that invasion takes place through the tonsils into the blood and lymphatic stream. Many have been led to look upon the tonsillar crypts as incubating chambers by which the body gains immunity. This is correct up to a certain point and explains why, when these organisms gain an entrance, they frequently do not produce acute but chronic conditions leading to mild response. Incubation of bacteria may proceed for years within the tonsillar crypts yet the defensive forces of the body may be quite able to deal with them on gaining entrance. As these forces are gradually reduced, the organisms steadily gain the upper hand. Toxins of bacteria act locally at a distance. Most frequently they act locally and it largely depends on the kind of tissue invaded as to the nature of the response. In highly organized tissue there is usually a breaking down of cells with little or no reproduction, whereas in connective tissue and other less specialized types there is irritation with overgrowth. This is well illustrated in syphilis, but not so fully recognized in other bacterial infections. To illustrate the action of bacterial toxins unassociated with usually recognized pathological changes I quote the following (*Medical Review,* Vol. xxv, No. 4, p. 96):

Prof. R. Massini writes concerning the results of an autopsy on a patient dying from myocarditis. A woman, aged sixty-eight years, had suffered for some time from symptoms of chronic myocarditis, but none of tuberculosis. The necropsy showed chronic, fibrous myocarditis, emphysema and edema of the lungs, mucopurulent bronchitis, fatty liver and congestion of the abdominal organs. Microscopical examination of the heart muscles showed badly staining nuclei and small granules of fat scattered throughout the muscle cells. Between them was much connective tissue. In some parts of the wall of the heart complete necrosis of the muscle was demonstrated, and near the surface of the heart the muscle fibres were infiltrated by leucocytes and showed fatty degeneration. There were no signs of pericarditis and in no organ were any changes found characteristic of tuberculosis. But guineapigs inoculated with heart muscle developed extensive tuberculosis, and the tubercle bacilli obtained in pure culture from the liver, mesenteric glands and an abscess in the abdominal wall of one of the guinea-pigs showed characteristics of the human type. The significance of this case is its demonstration that an apparently "ordinary" chronic myocarditis may be due to the tubercle bacillus, although none of the changes hitherto considered characteristic of tuberculosis were found. In the degeneration of these highly specialized tissues, pathological findings do not show inflammatory changes, and accordingly, doubt has been cast as to the cause of breaking down. Organs are largely composed of two or more types of tissue: A highly specialized parenchymatous tissue and a less specialized interstitial tissue. If the former is picked out there is usually cell destruction, if the latter, there is overgrowth. This is well illustrated in kidney and liver conditions. Such conditions as diabetes, pernicious anemia, leucemia, etc., are beginning to come under the ban of the infections, not from their pathological conditions, but by clinical findings, their constant association with infections, and the benefit derived by their removal.

Have we any right to assume any tissue in the body immune from infection and cell degeneration caused by their toxins? We recognize the ability of the spironema in this respect and must logically concede it to other organisms, particularly the streptococcus.

When it is borne in mind that in the majority of chronic infections, with the exception of syphilis and tuberculosis, the organism does not live and multiply in the invaded tissues. If the patient is going to survive, their finding and culture will be difficult, as their staining properties will be greatly impaired by the attacks of phagocytes and lysins. The late work of Rosenow, showing that under certain conditions the streptococcus takes on anaerobic methods of living and so cannot be grown under ordinary methods of culture, helps to explain much and opens up a great field for the explanation of what was obscure before. With the knowledge and experience already gained as to the action of these organisms in other parts of the body, must we not concede the same to the nervous system? The streptococcus must be regarded on the same plane as the spironema, but with this difference: The spironema if left alone multiplies indefinitely in the invaded tissues. The streptococcus cannot, if the patient is going to survive. That they gain access and do damage to the nervous system must be patent. Cases of myelitis and other spinal cord conditions, which are not specific or tuberculous, are not uncommon. Disseminated sclerosis is already being accepted as inflammatory. Dementia præcox and other forms of insanity are being proved clinically to be associated with these infections and cured by their removal. Personally I have seen some complete cures of epilepsy, following removal of focal infections, without any other treatment. One cannot expect cures in cases where much damage has already been done and fibrous tissue laid down. One often sees definite specific epilepsy cured or greatly benefited by specific treatment. These and many other factors make us pause and consider whether conditions such as paralysis agitans and obscure degenerations may not owe their cause to the same factors. We find diabetes responding in a marvelous way to the clearing up of focal infections, yet there is nothing pathological to support the infective theory, nothing but cell degeneration. We know that these cases are often specific and respond to appropriate treatment. Should we not test all doubtful cases by this acid test before going further?

The most important factor we have to recognize is that nearly all humanity is already infected with the streptococcus or allied organisms living under the conditions portrayed. The infection with these organisms is so prevalent that it has been looked upon as natural. Over sixty per cent. of all cases seeking medical treatment in big hospitals are suffering from diseases directly due to these infections. Three quarters of humanity are suffering from diseases that are easily preventable. They need not exist and will not in the near future. That is why I say we are now in a period of time in which the profoundest advancement is being made in medicine. As the largest breeding grounds for these invaders are located in the tonsils, teeth and nasal accessory sinuses, our attention must be directed thither.

So much has been written on these subjects that I shall emphasize only a few points. Tonsillar infection is almost universal. Every mother with infected tonsils passes it on to her family. If one child is infected all the rest are. Uninfected tonsils in the adult do not exist, unless they are completely atrophied and show no crypts, in which case the infection has died out. If tonsils are not infected they atrophy at an early age and there is nothing left for bacteria to multiply in. Every crypt is an incubating chamber from which invasion may take place and toxins be absorbed, but into which not sufficient of the defensive forces can pass to eradicate the organisms. Nasal infections are frequently secondary to tonsillar infections. Dental caries is often a sequel to tonsillar infection. Occasionally dental caries has been seen to cease abruptly after the removal of infected tonsils. Dental caries alone is not so dangerous as the result of dental work in the past. The writings of Rosenow are illuminating on this point and should be referred to. Many believe that in pyorrhea, as long as all visible pus and signs of inflammation are cleared up, the complaint is ended. One can easily realize that drugs cannot possibly penetrate by the paths taken by bacteria along the peridental membrane, and that in the majority of cases only extraction can eradicate the bacteria completely. The conclusions to be drawn are that until we can clean up this generation of focal infections, we must part with our teeth once they become infected, rather than face the dangers following closed infection at the apices. The almost universal expression of people who have had their teeth out is "I wish I had had them out before." There is no regret.

Most of the endocrine system is employed in the mechanism of defense; the thyroid, adrenals and pituitary, as well as the sympathetic nervous system. Constant overactivity for years in the presence of infections leads to their gradual failure. A case of exophthalmic goitre is an object lesson. Since the metabolism of life depends largely on the integrity of the endocrine system, it is not to be wondered at that men are old at sixty in the presence of chronic infections. The great wonder is that the body has such marvelous powers of recuperation and that it can go on so long in spite of all the evils which beset it. As long as repair keeps pace with destruction, one may be apparently sound. It is only when destruction outsteps repair that we show signs of the ravages being made. With most of our organs Nature has been unduly lavish. We have three or four times the amount of tissue necessary. Half of one healthy kidney is sufficient to carry on the normal functions of the body. It is not until so much damage has been done that inefficiency begins, that we are aware of any damage at all. By that time there has been great destruction.

In regard to bowel infections, although the intestine teems with bacteria, it has not been my experience that much damage originates from that source, unless there is gross stasis. It is not uncommon for the bowel to be infected from some focal infection; colitis is occasionally of this origin. Appendicitis is probably more frequently due to metastasis than to any other cause, and in mild cases the removal of the focal infection should be tried before resorting to operation. Gallbladders, although in many cases infected from focal infections, become eventually focal infections themselves. Many of the failures in the cure of diseases due to these infections can eventually be traced to some such hidden foci.

There is another aspect in the danger of focal infections. A family of children catches cold, one or two have bronchopneumonia and possibly one has empyema. All have had the same initial infection. The cause of the bronchopneumonia and empyema are not the direct result of the colds, but of a flare up of the chronic tonsillar infection. The initial infection of the cold temporarily lowered their resistance to the other organisms. Exactly the same reasoning must be applied to the secondary infections in the late influenza epidemic. A child with infected tonsils who catches scarlet fever will run a far greater danger than one without. The extent of these infections and the infinite possibilities of damage due to them overwhelms every serious thinker. Syphilis is an object lesson, also tuberculosis, but whereas only a certain proportion of the population is infected with syphilis and tuberculosis, nearly the whole is infected with some focal infection. Outside of syphilis and tuberculosis focal infections are practically the only source of gross damage to the human body in temperate climes.

If we recognize the ability of these organisms to destroy highly specialized cells and to cause over growth in those less highly specialized, we must consider the possible part played in the production of unlimited overgrowth. When we find signs of cell response in any tissue, be it brain, nerves, bloodvessels, or any tissue capable of reproduction, we ought first to consider the possibility of its being due to the presence of some organism. It is only necessary for the body to have lost its powers of defense against a certain organism of low virulence, which has a selective affinity for a tissue and the powers of reproduction to get unlimited overgrowth.

In summing up one arrives at these conclusions: Mankind is almost universally infected with a group of organisms, living in sheltered places, yet invading the body and causing damage by their toxins. These processes can go on for the best part of a lifetime. The defense mechanisms may be able to deal with the invasions for varying periods of time, depending on the virulence of the organism and the powers of the defense mechanisms. Highly specialized tissues with a limited power of reproduction or none at all are slowly destroyed, while tissues of the connective and epithelial type are caused to reproduce by irritation. No body tissue is immune. The breeding grounds of these organisms, fortunately for mankind, in the majority of cases, are such that they can be easily cleaned out. These infections are capable of doing as much damage as syphilis and in many respects the results are very similar. They are a bigger menace to the community than syphilis, because they are tolerated. Clearing up of these infections is slowly taking place, with a view to relieving people already damaged. But consider what it would mean to the coming generation if such infections could be entirely prevented.

Reinfection of Tonsillar Remnants After Incomplete Tonsillectomy

A Report of Four Cases

By JOHN A. GLASSBURG, M.D.,
New York,

Assistant Attending Laryngologist and Otologist, New York City Children's Hospital; Surgeon, Ear, Nose and Throat, Stuyvesant Polyclinic; Assistant Visiting Laryngologist, St. Joseph's Hospital.

Although it is the common experience of general practitioners as well as of rhinolaryngologists to find remnants of tonsillar tissue after incomplete tonsillectomy, reports of the deleterious results of such incomplete operations are scant in the literature. Undoubtedly the day of the tonsillotomy is past, and the rank and file, as well as the vast majority of the authorities, advise and practise complete enucleation of the tonsil. Therefore, with the few exceptions in the cases of those operators who still deliberately cling to the partial removal of the tonsil, tonsillotomy today means a tonsillectomy incompletely performed. Of course, there are certain cases wherein, because of sudden supervening conditions, such as hemorrhage, asphyxiation, or shock, the operation is purposely hurried, a termination is rapidly sought, and the complete removal of the tonsils is necessarily abandoned. These emergencies, however, are rare and if caution and a certain degree of skill are shown, especially if time is given to the inspection of the cavities after the removal, the tonsils as a rule can be enucleated *in toto*. The rapid grandstand play removal without inspection of the cavities cannot be too severely condemned, both from the viewpoint of tonsillar remnants and the possibility of a subsequent hemorrhage from a small spurting vessel that may need ligation. To emphasize the necessity of this painstaking skill, and the examination of the cavities for small pieces after the removal of the tonsils, the four cases constituting this paper are reported.

Case I.—Jane M., twenty-four years old, since childhood had been suffering every winter with acute tonsillitis, getting three to four attacks during the season. On January 10, 1919, she was operated on. According to her statement local anesthesia was employed and she felt well for four months and then got a sore throat but only on the left side. The attack lasted the usual week, during which she applied cold compresses, took aspirin, and gargled with the old reliable "yellow throat mixture." During the following summer she was well, but with the approach of autumn she began getting frequent attacks of sore throat, but always limited to the left side. I first saw her during one of these attacks which was sufficiently virulent to confine her in bed with a temperature of 103°.

Examination of the throat showed a piece of tonsil tissue about the size of a walnut at the inferior pole of the left tonsillar cavity. Upon this piece of tonsil was the typical yellowish patch. The rest of the cavity as well as the right cavity was perfectly clear. I waited for the subsidence of all the acute symptoms, and on November 20, 1920, under local anesthesia, removed the offending piece of tonsil. Since then, to the present day, there has been no recurrence of the tonsillitis.

Case II.—Alfred P., eighteen years old, suffered for about four years from indefinite pains in the joints. In addition, he had recurrent attacks of acute tonsillitis every fall and winter since babyhood. He had gone to an orthopedic clinic and after elimination of all possible foci of infection, the tonsils were removed. General anesthesia was employed. The operation was done in July, just after the close of school. The boy felt perfectly well until the autumn, when the sore throat and the articular pains returned. During one of these attacks the throat condition became so severe that the boy could not open his mouth more than three quarters of an inch. It was during this attack that I first saw him and found a peritonsillar abscess on the left side, a piece of tonsil about the size of a small hickory nut at the superior pole of the left cavity, and two small pieces of the tonsil, one at the inferior and one at the superior pole of the right cavity. The remnant in the left cavity was an angry red. The abscess was opened and when the acute symptoms subsided and the throat returned to normal, the tonsillar remnants were carefully dissected and removed. It is now about two years and the boy has had no more throat infections and the arthritic pains have disappeared.

Case III.—Angelina S., twelve years old, gave a typical history of tonsillitis followed by arthritis and terminating in endocarditis. This had been going on for several years. An exact history could not be obtained because of the mentality of the parents who were illiterate Italians of the poor peasant class, who could not speak a word of English, nor could they make themselves understood through an interpreter. All that could be gathered was that the child would get frequent sore throats, that she had attacks of pain in the joints associated with high fever, and that the doctor had once told the mother that the child had rheumatism of the heart. Three years ago she had had her tonsils removed and the mother stated there had been a great loss of blood immediately after the operation, and a hemorrhage six hours later, which necessitated the doctor's staying with the child for two hours, during which time he applied various instruments to the throat. It could not be ascertained whether a stitch had been taken in the tonsil. After the operation the child had no more attacks of sore throat, but the rheumatic attacks persisted and she complained of a constant sticking in the right side of her throat.

The child was referred by the family physician who had discovered a peculiar condition of the throat. This condition consisted of adherent pillars on the right side enclosing a small ballshaped mass the size of a walnut, and a small piece of tonsillar tissue at about the middle of the right cavity. The child was anesthetized, the pillars were dissected and separated and a piece of tonsil was found between them. This mass and the mass on the right side were removed. The "sticking" in the throat which was due to the pull of the adherent pillars was completely relieved. The child was under the observation of her physician for one and a half years, during which time she did not have a single attack of acute arthritis, though she would complain of occasional pains in the joints, especially during rainy weather. The endocarditis persisted.

These four cases have been selected because of the obviousness of the cause and effect in each instance. The author, however, has seen a great many cases wherein remnants of tonsils have been left over after tonsillectomy. The majority of these remnants are at the inferior pole of the tonsillar cavity. This is probably due to the difficulty sometimes experienced in separating and dissecting the tonsil from the pillar at this point, for the plica tonsillaris which covers the anterior inferior portion of the tonsil is often attached to the tonsil at this particular site. If Hurd's separator is employed and the anterior pillar gently drawn away, the cavity can be readily inspected and any piece of tonsil tissue adherent to the plica easily removed. Though many of the patients who have tonsillar remnants do not have any subsequent throat infections, the fact that some do, as demonstrated by the cases reported, is sufficient warrant to make an appeal for the complete enucleation of the tonsil.

231 East Eleventh Street.

The report of another case will appear in the author's reprints.

Poor Fish and What He Got for His Pains

By HE WHO GETS SLAPPED, A.M., M.D., Ph.D.

Recently I went a fishing. I was gone a long time and fished unremittingly for protracted periods. It was an old and wellknown fishing ground. I had been going there for thirty years. In a manner of speaking, it was a family fishing place, although out on the open and the deep sea, and I, my fathers, and their forefathers, had been casting their lines into this great sea and the catch had never ceased and its variety never ending. Each time I go fishing there I get a basket full of new things and although we have a long series of family traditions about the possibilities of the catch, each trip rewards us with something apparently never caught before.

I remember on the occasion of my recent trip I brought back a lot of those queer fish. There was a large meeting of my friends, friends in the sense of the word that they all claimed to be ardent fishermen like myself. In my enthusiasm I told them what a fine catch I had, and invited them to see my catch, these queer fish of mine. This lot, I told them, were only some selected from the others which I thought would interest them, the codfish, and the mackerel, the squids and the bluefish, the shad and the bass, why they were old acquaintances, I had left those behind; we had used them for our daily consumption —they kept us alive on our trips—but here were some rare specimens.

Even before opening my basket some noses were going up and their owners were edging themselves out to the edge of the crowd. "What a smell they have! How unpleasant! we have more sensitive noses than the rest of you fellows; you can stay if you like but, excuse us! Besides there is a rubber of bridge to be finished and we need the money!"

Certain eyes were watering, too, the salt water I suppose—a sort of contagious magic, or would some of the modern wiseones just put their thumbs in their buttonholes and say—"suggestion, you know"—at any rate, with their watery eyes and their sniffly noses, it became not so pleasant for them to look—at least not for long, and so they soon excused themselves—they had other fish to fry that came from fresh water, and moreover such did not seem to have the same effect upon their sensibilities. A protein sensitization, undoubtedly of some occult type, I presume, would be the orthodox explanation of the difficulty.

Finally a loud guffaw came from one corner of the group: "My word, Æscy!" (the sch sound was pronounced with that soft accent, as in shutter, instead of sch as in school, as perhaps my more pedagogic purity might have liked), "you don't mean to hoodwink us like this, do you?" Shad evidently was the conditional reflex that led to his socalled complex as those Vienna fellows, those Freudians, would say.

---

*A family physician and well known fisherman of bygone days.

"Fish! My word! Æscy thinks he can put the scales on our eyes! Why he's manufactured these; he never went fishing at all!" and in righteous indignation and with a curl of contempt on their lips, that dimly betokened how badly they felt that someone would tamper with their sense of the infallible, another quarter of the company retired to play the old game, newly christened Fatu Liva (1), that came from the Filbert Islands, discovered by that intrepid crew on the Cruise of the Kava. The nest of Fatu Liva that was a real thing—this—what a fakir old Æscy was! Who would have guessed it, and such a plausible story that about the great time they had, and the family fishing ground. But they were wise. They were practical men. What a wonderful bird it was that laid square eggs with black dots on them all different, from one to six.

But what a rustling there was as they turned away. They had me on the griddle there for a while. It was in vain that I explained how simple the whole thing was—"here they are, I just brought home a few little things that interested and amused me, and here they are. Of course, I hardly would have brought them if everybody knew all about them, although," and here I know I was malicious—"I have *occasionally*" —I said this last word loudly, as it were to soften the after coming sting, "I have observed that the only thing you may be interested in is something that everybody knows all about. I imagine it gives us all courage to talk about what we know, when we know the other fellow told us about it—it helps us both, to repeat to each other what we have told each other; a kind of a mutual selfappreciation society." To dispel a gathering sense of disapproval of my levity, I put my arm on their shoulders, in a friendly way, and gathered them around the table on which my prizes were gathered. I felt at the time it was selfish, that perhaps they really were not interested in my catch. Why should they be? for were they not all falling into small groups explaining just what kind of flies they used in August; or what a great help a cloudy day was for bass; or how they never fished quite so deep; they never had brought up anything but suckers and—the rapid side glance had a wicked motion, and their voices dropped a bit at the name of this nondescript fish of many coats and colors. And they argued and argued, now coolly, now with warmth. The dance of the atoms as portrayed by our chemical friends had nothing on the movements of the remaining groups as they almost bounced away from my specimens, in their own argumentative preoccupations, rather than walking up to them and turning the things over.

Again an inkling of my own stupidity came into my mind. "Of course!" I said to myself, and then in an ameliorating way said: "Cat fish? sure! barks? cert! You should grab them like this," and I proceeded to take one up, but my ruse was suspected. They were not ready to look at the fish. They knew all about the precautions to be taken in handling cat fish.

Again I started. There was a bucket of sand, nice yellow sand, and now I announced, "You get your hands full of sand, and the eels, the slippery devils." Now I was in for it. Slippery devils, dialectic I think the logicians call it. For hours the arguments waxed and waned; the illogical qualities of all hard propositions (barbed cat fish) and all pragmatic hypotheses—these I learned were the philosophical correlates of what I in my more simple way was calling eels. "But! look at them! here they are! I will even consent to announce they have nothing in common with catfish, and only the faintest resemblance to eels. Slippery, no doubt, that I can't deny, and with dangerous horns, even a novice might see that, but let's stop all this cackle about what isn't and see if we can get anywhere with what is."

Even then, blind fish that I was, I could not see that perhaps after all no one in the crowd had ever seen these particular specimens, and I was more foolish in urging them to take a look at the unknown than they were in refusing. A jingle came into my consciousness: "Be not the first by whom the new is tried, nor yet the last to leave the old aside!" I know that phrases, like old fogies, morons, stupids, were all too ready to leap to my lips. Probably, I dimly guessed, as a defence for my wounded vanity, for now the groups were getting further and further away from the table, each discussing about fish they had seen and apparently they seemed to be interested—old, old timers, certainly were among the last to leave the old aside. A discomforting thought! How old the new, how new the old! and smiling through the sarcastic muscular distortion—it must have been really diabolic seen in the mirror of the eternal—with cajoling phrases I sought to enlist their interest in my catch by the old trick of assembling the resemblances. This might make them my friends. If they could rerecognize what they already knew. Then it was no longer new, but old, and presto, shades of Heraclitus, Protagoras and Hegel! I had resolved the irreconcilable, opposites were equal, and they would believe that I really had been fishing. This was of the catch, and they need not fear its newness. Novelty would not be dangerous, and I would be happy.

No! blind fool that I was, even now they avoided looking at the catch.

Persuaded, as my excitement while fishing had convinced me, here were new fishing depths—here were things catchable—even if different, and yet not so very different; even getting ready to knock my friends down if they did not look—surely the best method possible to defeat any cometogetherness—what better procedure now than to play the great old camouflage, shrug the shoulders, walk away. There they are you know! nothing much! Just a few little curiosities! Not so very important!

"Interested?"

No? "Sensible old chap." "Yes! Oh, I don't know. Why waste your time?" "Speculation! a quagmire, any old fool can speculate; a losing game, stick to facts, my boy, solid facts." "Why you know that editorial in the *Journal of the A. M. A.?* Now there you have it." "Facts. Everybody agrees about that!

Bergson? What did he say, you ask? "When everybody agrees about a thing it is dead, no longer evolving, but passé." Why, he's a silly Frenchman! All Frenchmen are silly. Besides they have such disgusting toilets on the Boulevards, right in plain sight! "No! Stick to the English, they are sound, very sound." "Why they have castles in the same family for a thousand years." "Believe me that right little, tight little island stuff!"

Yes, I mused to myself, keep away from the table, don't touch on the matter! Get your emotional rapport. People are children. Amuse them; flatter them. Then perhaps they will look at your fish, a side glance it may be, even that will act on the memory, and finally the resistance will wear away, and maybe one day they will pick up one of your old fish anyhow and say: "Great." "Why I remember some thirty years ago I got one of those." "It was new at the time, but dear me, no one believed me." "You know, I was the first man really ever to find this particular specimen." "Believe me, it made a furore in its day, but like everything else, forgotten, and here Æscy turns it up in his catch and pretends it is new." "Why old Homer knew all about that." He just took it out of my mouth as he told us the Kipling version of it:

When 'Omer smote his bloomin' lyre
He'd heard folks sing by land and sea
And what he found and most admired
He took and used like you and me.

This was all he could remember, and musingly, in quiet mood, I went on:

The market girls an' fishermen,
The shepherds an' the sailors, too,
They 'eard old songs turn up again,
But kep' it quiet—same as you.

They knew 'e stole; 'e knew they knowed.
They didn't tell, nor make a fuss,
But winked at 'Omer down the road,
An' 'e winked back—the same as us!

How I then wished I might have been as blind as Homer, maybe then I might see.

No one had looked at the catch. They all came it is true, but one by one, in groups, in twos and threes and singly, each to his own, and bitterness crept into the heart. "What's the use?" "I'll go to the market place where people are hungry"; "I'll tickle the palate for novelty"; "I'll show them and reap golden rewards." Even then, my blindness had not permitted me to see that that was just what they all were doing, but with the old familiar ruses. The bridge players! They knew the gambler's chances. The Fatu Livas! why! and here I almost cracked my sides at the thought of the loaded eggs, supposed to roll, but like the eggs of yellow hue, they too are loaded, the greedy get the shell and the world rolls on!

No, I will not destroy them, I will not take them to the market place. They came from the sea, they are a part of Nature. What can they tell *me, myself?* Not, How can I be made great in the eyes of my fellow fishermen? but rather how can I be made content, within myself, and go on fishing, not as a showman, but just to fish. For fishing is fun!

Quackery de Luxe: A Form of Medical Charlatanism Known as Orificial or Constructive Surgery*

By JOHN F. W. MEAGHER, M.D., F.A.C.P.,
Brooklyn,
Neurologist, St. Mary's Hospital; Consulting Neurologist, Kings Park State Hospital, Rockaway Beach Hospital.

Because nervous and mental patients are particularly likely to be victims of this form of quackery, I decided to make a study of it.

I had my attention first drawn to this cult a few years ago when caring for certain patients suffering from insanity, who had been "treated" by certain socalled orificial surgeons. I made some investigations and gathered much of their literature—if one can call their writings by so dignified a name. The result of my observations I will place before you. It is true that a large part of our profession do not know about these quacks, who are especially dangerous to the health of women patients. While many of them have medical degrees, few, if any, are members of reputable medical societies. They carry on their work and propaganda through church clubs and women's societies. They have grown in numbers recently, and even conduct what they call sanitaria. In Chicago they also publish a medical journal. Much of their literature is written in a style full of superlatives and bombast—there being just enough medical terms—wrongly used—and a hypocritical pseudoreligiosity to deceive certain unfortunate invalids and their relatives.

One of their first victims whom I saw was a girl, a case of dementia præcox, who had been for years in the Kings Park State Hospital and was so badly deteriorated that she looked and acted more like an animal than a human. One of these socalled doctors wanted $150 to operate on the girl's clitoris. The next case I saw was a nurse complaining only of a headache who refused to permit any operation on her clitoris, but who submitted to rectal dilatation —"to get the poison out of the system." She committed suicide shortly afterwards. The next case I saw was a nineteen year old girl, feebleminded and epileptic, who had already been in Johns Hopkins Hospital. She was stretched on a table—for what reason it would be hard to say; had autohemic treatment, some of her own blood serum being reinjected into her, and was mutilated by having her clitoris and nymphæ amputated. Her credulous father told me she had been "circumcised." Immediately following this operation, she went violently insane. And yet the "operator" had the audacity and indecency, weeks later, while she was under my care, to leave a pseudoreligious card for her, writing to the little girl, now insane . . . "whose inner self is noble, sweet, and large . . . freed from the earthtime temple . . . no longer bound by the material fetters." These hypocritical words are meaningless, but have an emotional value to temperamental people. Another one of their victims committed suicide by jumping out of a window. We never hear of those wrecks who just go back home. One cannot imagine the emotional hold some of these quacks have on the families of the patients. The father of one girl asked me if I would hold a consultation with one of them about his daughter, but of course I declined, telling him we did not consult with frauds.

---

*Read before the Italian Medical Society of Brooklyn, October 3, 1922.

They especially pretend to treat chronic cases—which type are the usual dupes of quacks. Even educated people fall into their net. A relative of a certain college president, doctors' relatives and others have been victimized by them. One minister's wife had her clitoris removed and was an invalid after having this done.

Now what is this orificial or (as they euphemistically, even though falsely call it) constructive "surgery"? The idea was concocted and developed over thirty years ago. "Constructive surgery is a recent naming of orificial surgery, because it is always constructive, never (!) destructive. It is not always surgical." Mutilating a girl to them is not destructive. Their victims suffer not only financially, but worse still, in body and mind. Very constructive indeed. "They are called orificial because they free the sympathetic as well as the nerves of sensation from trouble." The dictionary defines orifice as an opening or aperture. But why should quacks be dominated by dictionaries?

Originally they admitted only "doctors." But (vol. 8, No. 4, p. 50) later "we admitted to our association members of drugless schools" (i. e., osteopaths and chiropractors). Their "greatest doctor" had his medical license rescinded for this nefarious work. Naturally they could not see that this was proper, and said that a "scathing denunciation should be made for this."

They ask "What about the body below the belt?" . . . "There is a crying need of pelvic operators." From their literature, one guesses that for these burlesque doctors, there is no other part of the body. They say, "The lower orifices of the body therefore (are) the gateway to life." Their audacity transcends that of all other quacks.

And again as to the nature of their work, we find this in their official journal (Vol. 7, p. 222): "So much was said about rectal work, that the idea prevailed that orificial work meant surgery of the rectum alone, when, in fact, as we all know, it included surgery of all the lower orifices." A frank admission that the nose and mouth as orifices are unimportant. Further on, we read, "It has been noted that irritation of the lower terminals of the sympathetic (about which genuine scientists know little, and these ignorant charlatans, nothing) affect the emotional, moral, and religious side of man more than do those of the upper terminals or orifices." Evidently orifice—i. e., an opening—means the same as terminal to these barbarians of English.

They say that millions need circumcision and operations on the rectum, to be saved from ruin. Thus as a wish fulfillment, their victims loom large on the horizon! Another writes that this cult is one of the largest reform movements in progress today. A real reform, of course, would be to put all the members of this cult in jail.

Following out the true quack way of doing things, they pick out a field of medicine but little explored, and make very "wise" deductions. Their writings show they are pathetically ignorant of the sympathetic nervous system, yet they talk, or rather just use words, about it glibly. The poor victims, unfortunately, cannot detect the spurious nonsense in all their sayings.

Here are a few samples of their ridiculous jargon: "Free the sympathetic nerves from the impingements and handicaps of all kinds." Again, "The orificial method relieves and avoids the impingement of sympathetic nerve terminals."

Another writes, "By the history of the case, we find different ailments which come from branches of the sympathetic, and they are one by one corrected." It would be a much less impossible thing to do to tag every hair in the head, than to follow out this procedure. And, "All points of nerve impingement should be recognized and removed." Impinge on what, and remove from what? Of course, this is sheer nonsense, but one must not be too analytical in going over quack claims. Their purpose is to cajole the public, and they know that some of the public want to be fooled, as both Abraham Lincoln and P. T. Barnum stated.

On the cover of their "Journal" is printed in large letters, "We live or die as the sympathetic nerve waxes or wanes," and also, "Study the waste and repair of the sympathetic nerve." On top of this important dictum, one of their number writes (vol. 8, no. 4), "There is no one who can tell what the sympathetic nerve is going to do in the next ten minutes or what it has done in the last five minutes." Which one of the thousands of branches of that system is referred to is not told. But, of course, these rascals care little about being particular or accurate. This next writer, however, sticks closer to their battlecry, "As I listened to this profound paper, I could almost see the human form divested of all material except the sympathetic nerve." (Vol. 7, p. 235.) This enthusiastic statement was written before the days of prohibition.

What any medical man can make out of this title of a paper in their journal is hard to say: "Spinal Foramina as Waster of Sympathetic Nerve Energy."

In another place in speaking of the sympathetic, one is directed to inspect and care for every branch. About as easy an injunction to follow as it would be to inspect and study every pebble on the beaches along the Atlantic Coast.

Another writes that he is so pleased with the course that, "there is not enough paper in the world for me to write on to tell you . . . that the one great system is the sympathetic . . . It's the goods." One can imagine the quality of research work this cultured gentleman employs in dealing with the sympathetic and vagus nervous systems.

One need hardly say much as to the chief motives which inspire these quacks. I know of one who gets $150 to $300 for a needless operation on the female external genitals—a socalled circumcision. That money is their chief objective, one can see from reading their circulars. They are told to understand the patient "physically, temperamentally, and financially." "The course has made me a better physician from every angle—even to the pocket." Another writes about "an increased income with less irksome toil." An advertisement recommends to buy a "tension" table (on which to stretch patients) and thus to double your income and lessen your labor.

Like all quacks they are wonderful at propaganda.

They circulate a booklet "in lots of hundreds of thousands, and await results." They say for the propaganda to be effective, their advertising matter must be distributed by the hundred weight and tons. While in 1919 they only had a hundred "alumni," yet they speak falsely of "thousands of physicians who declare orificial measures to be the sheet anchor in such cases." Physicians who do not use their nefarious methods, they declare to be "no good."

One is not surprised at their statement that "one of the most flourishing osteopathic institutions in the country makes a feature of orificial surgery."

They describe their opportunities as a "wonderful and unlimited field of endeavor." They request prospective "students" to enroll before June 1st, in order to graduate with the September class. They say that the course is so condensed and simplified that "you have the knowledge in your head and not in your library." "So master each lesson . . . and immediately apply the knowledge." "Many of our students have become very proficient orificialists merely through their mastery of the correspondence course, and have not even attended an orificial clinic." "We have no dissatisfied students. Join us. Sign the blank." "You pay $125 for the course; only $100, if cash is paid at once." This payment is the only important requirement to take the course.

One old socalled doctor of seventy tells them to send some application blanks; "I believe I can get some of the boys to start studying the course." Rather old to begin such villainy; but the lure of gold knows no age.

The medical sciences of gynecology, urology, proctology, neurology, etc.—any one of which takes years to thoroughly master—are all learned in twenty correspondence lessons by these knights of fraud—and they assert they are even more proficient than are regular doctors in these specialties.

Their language at times is not only ambiguous but is often unintelligible. They undoubtedly think, however, that it sounds very convincing to the public; e. g., "Life force originates from cell intelligence." Again, "We assist our students in analyzing and classifying defects and their reflexes."

One is rather startled by this piece of wisdom that indefinite conditions remain mysterious till "traced and located in some obscure pathology of the rectum . . . the most profound and disastrous conditions are of metastatic character, which leaves the origin devoid of active evidence."

Listen to this captivating piece of nonsense—"The story from pelvic irritation to the premature grave is by way of defective children, immorality in schools, physical invalidism . . . acute and chronic diseases, white slave trade, insanity, and criminality. . . . Pelvic workers will at such time come into their own. . . . Speed the day."

They advertise that orificial surgery improves the circulation thus—"The blood stream will carry life and joy with benefits to the spiritual, mental, and emotional natures, noble aspirations and constructive courage." This jargon sounds as though it was borrowed from another well recognized form of quackery founded by a paranoiac lady. Only this cult makes all illness and even lack of financial and social success as being due to need of rectal dilatation and circumcision.

These frauds prey on the fears of certain mothers. For they say circumcision of the girl or woman of any age is as necessary as for the boy or man. (Women, particularly, are their victims.) "If not performed when required a girl's life cannot be normal." Here they make a strong appeal for more victims and pari passu for more money.

One of them writes, "First and foremost, examine all rectal and anal canals, because we must get the experience." This appears to be the only sort of experience they seem to care for. Another says, "I have been astonished at the multitude of sins concealed within the rectum." Sin is a transgression of a rule of rectitude; according to their philosophy, the home of rectitude must be in the rectum.

I am sure that we will all agree that the most dastardly of all quacks are those who deceive the relatives of the victims by a hypercritical pseudoreligiosity, which is nothing short of being sacrilegious. This is one of their strong points to further their own nefarious ends.

So it behooves clergymen to become acquainted with these frauds, as their victims are chiefly good. confiding religious people, whom they reach by means of booklets sent to members of church societies and women's clubs. In the booklet distributed by them we read: "Many a clergyman sends his charges to a physician, only to have them returned in worse condition than when sent there, because the physician being ignorant of these matters—(of which these correspondence quacks are all wise)—tells the youth that he is all right, thus adding hopelessness—at whose door does the sin lie—at the youth's, or at the doctor's?" And further we read, "In the great wave of moral reform—the laity should demand this skillful attention to the lower orifices of the bodies of their children." And one of their lady members writes that "rectal and genital treatment in children is more important than attention to their eyes, nose and throat." In another place they write that as a result of their treatment "the body shall be released from every fetter that binds, that the spirit shall be directed Godward." Comparing this to the note written by one of them to one of my patients who went insane after a lady member of this cult mutilated her external genitals, it looks as though they used a certain pseudoreligious formula in talking and writing to their patients.

In another place we read, "See the heartbroken mother as the . . . (orificialist) extends the unmistakable glance of sympathy, courage, etc." And also, "This boy's physical handicaps were surgically removed, and he awakened to a threefold new life." If their method of circumcision of a male in any way resembles the circumcision which they did on one girl whom I subsequently examined, then that male should fold his "tent like the Arabs, and as silently steal away." For he would not even know himself. And again, listen to this, "Truly, as is declared in the Hebrew Scripures, 'The blood thereof is the life thereof,' and it has been shown [?] that the blood under constructive surgery is instantly improved."

One writes (vol. 8, p. 68), "They call orificial surgery bless-ed." (Note the spelling.) Another says, "Sin and sickness are synonymous terms." Another one states that "If vice conditions continue to increase in the next fifteen years in the same proportion they have in the last ten, we shall be a nation of incompetents."

"The child's body . . . find physical conditions that make it impossible for him to have a clean mind. When parents, instructors, and physicians in general come to recognize these physical irritations, they will forgive criminals," etc. A good prepuce and a perfect rectum evidently ought to be proof against crime; at least should confer immunity against a jail sentence.

The orificialist "proves all things and holds fast to that which is good." (A moneyed patient, of course, is bled white.) From a "reprint" we read, "His body . . . cleansed of its physical irritations . . . then shall he, this TRIUNE EARTH MAN be lifted up to an at-onement with the Triune God." Truly, wolves in sheep's clothing. They say that by removing irritation from the pelvic organs "many liars can be made truthful, thieves honest," etc.

It was a tedious matter to go through their "literature" to get some of their ideas on physiology, pathology, and diagnosis. Without a word of exaggeration one sees nothing whatever but references to the rectum and external genitals. Other organs in the body from their viewpoint, are apparently there through courtesy, and of no particular importance. And they only are good observers. For we read, "Physicians—i. e., regular doctors—often do not know what a normal anus and rectum should look like."

They use a table for stretching patients—"while the body is under tension, which compels all the muscles of the body to relax." Though foolish, this is certainly a novel idea ,and keeps all the poor victims returning regularly to be stretched. One of the leaders of this cult in an article on pelvic hygiene says that "pelvic conditions not only dominate the form of respiration and the heart tone, and hence the oxygen supply (and) tissue metabolism." Also that the rectal and vaginal sphincters by "their close nervous association with the middle coats of all the tubes of the body, seriously handicap abdominal respiration."

The following will be news to most doctors. This writer says that in nine out of ten chronic cases, if the patient is asked to take a deep breath, the doctor will feel no motion in the abdomen; this "shows conclusively an impeding of the sympathetic branch which supplies the diaphragm—the cause of which is very often found in rectal irritation." Certainly these quacks are irresistibly drawn to this region—no matter what the excuse.

Another writer states, "The normal exhilaration felt after a normal stool is due to the message of *bien être,* sent by way of the rectal respiratory reflex arc to every tissue in the body." Another one writes that after a rectal operation "the patient left his crutches; could run . . . and now uses his fine baritone voice." Here is a clue for one aspiring to a grand opera career.

"Faulty metabolism is caused by impingement of the sympathetic nerves at the rectum." (Vol. 8, p. 78.) It would be futile to go on quoting from these quacks just to refute their absurd principles. The nonsense of their sayings is sufficient for this purpose. I merely quote further to show the arrogant audacity of these comedians posing as doctors. One writer says, concerning operations on the rectum (p. 238), "Specula or packing must be removed so that the patient can breathe." Another writer says that the "trivalve speculum (in the rectum) stimulates peristalsis, and enlivens both nervous systems and flushes the capillaries of the body inside and out"; wherever that may be. Possibly they have fashions in speculæ—for winter or summer breathing.

Here are a few other quotations: "Peristalsis performs all the chores of the body, except chemism." (Vol. 7, p. 224.) "Give the sympathetic nervous system a chance." It would be better to give the patient a chance—to escape. "I will not talk of chemism, though fascinating it may be." (Vol. 7, p. 231.) "Crowded teeth, preputial adhesions or rectal pathology will inhibit or accelerate peristaltic rhythm. Spinal impingement will do the same." (Vol. 7, p. 234.) They omitted to say that sitting on the North Pole would also do the same. Another gem is this: "In the study of the rectal reflexes, the fact that the sympathetic nerves do not decussate simplifies the matter of tracing through the trophic and also the cerebrospinal nerves."

No one—not even the writer—could understand this. "The personal observations of the writer indicate that rectal disturbances act most frequently through the commisural fibres to the ganglia and plexi of the trunk, and so are more frequently responsible for profound nutritional changes; whereas the reflexes from the sexual organs are more frequently referred to the cerebrospinal fields. This . . . may not be true, for one man's experience is not sufficient to establish a conclusion." One wonders why the writer, after getting off this awful stuff, becomes so modest at the end—surely not because of shame. Possibly because of fear of drowning in his own pathological brilliancy.

But to go back to the reflexes—the real facts about which are evidently a closed book to these quacks. This writer says that the course "has taught me where to look for the probable origin of pernicious reflexes . . . to remove them . . . and to crowd them out with the therapeutically elicited reflexes."

Another writes, "The lower portion of the rectum, the home of the reflexes." This is the first time we ever knew the reflexes were domiciled in a regular home. And the other reflexes of the body—those of the skin, eye, pharynx, etc., certainly would need a guide to return to a home they never knew of before. By now, no doubt, you are quite convinced that these jolly "doctors" are little concerned about such valueless organs as the heart, lungs, etc. The writer of the paper called The Rectum as a Therapeutic Field says that the nerves of the rectum are connected with the other nerves of the body, "Hence the therapeutic field of the rectum comprises the entire body." One can imagine how this "professor" would remove a foreign body from the eye.

A writer who puts A. M., M. D., F. S. Sc. Lond. after his name, asserts that in nearly all diseases "there will invariably be found more or less irritation of the rectum, or the orifices of the sexual system, or both. This proposition was given by Dr. ——— (a leader of these quacks), with a liberal reward offered to anyone who could refute it. A generation has passed with no one claiming the reward."

They are wonderful diagnosticians, as the following will show. "Irritable children, kicking off the covers (means) very likely clitoris or prepuce trouble. Pain . . . down the sciatic nerve . . . very likely trouble in the rectum. . . . I am enthusiastic." One is glad that he didn't say intoxicated or psychotic.

What do you think of the mental state of the charlatan who writes this scientific *bon mot?* "If the irritation to the clitoris is from an abnormal hood, the nerves are excited to the extent that the sympathetic nerve waste is sufficient to interfere with the circulation, say to the intestines, by way of the pudic to sympathetic pelvic plexus . . . because the function of red bone marrow and spleen and liver are not able to do their work, and you have a functional sick body . . . find the cause, clitoris." Another writes, "There is frequently a varicose condition of the vagina, uterus, and perhaps also of the lower rectal inch." From their writings one would get the idea that they measured this important organ, the rectum, in feet, yards or miles, rather than in inches.

In reviewing their methods of treatment, you will notice that not only all diseases, but even family squabbles, untruthfulness, etc., are treated via the rectogenital route. Apparently they know of no other method of procedure. To give a brief idea of the scope of their work, I quote from their booklet:

"Anemia, angina pectoris, asthma, chorea, chlorosis, constipation, dementia præcox, chronic diarrhea, enuresis, epilepsy, goitre, hay fever, insanity (any and every kind, of course), lumbago, marasmus, necrosis, neurosis, neuralgia, neuritis, neurasthenia, paralysis, tic douloureux, torticollis, tuberculosis of bones and other tissues, latent syphilis, varicose and other ulcers, and many other deep seated, stubborn conditions are intelligently managed in the light of orificial surgery." And further on we read:

"Temperamental and emotional diseases, dyscrasias, temperaments, tempers, perversions, lowered vitality, impotence, sexual incompatibility, nymphomania, inordinate erotism, kleptomania and other criminal tendencies, delinquency and all affections of emotional origin can be approached, analyzed and treated, and cures effected by the thorough orificialist." And to think of it, all this accomplished by dilating the rectum, and nipping the prepuce in the bud. Why did they omit tightrope walking? But even the above does not exhaust their capabilities, for we read further that "Cases amenable to the application of constructive (?) principles are found all the way from the unmanageable little girl to the insane woman; from the foolish, hysterical adolescent girl to the loadstone wife; from the slightest anemias to the pronounced tissue changes; from the tiniest discrepancies in character to grossest immoralities; from the slightest home inharmonies to the divorce court; from all forms of human suffering and disease to health and happiness."

Here is a case report by one of their artists. "With fear and trembling I began dissection of the pus sack (spelling his), and when I got through, I had a whole in the buttock as large as a baseball. I kept the patient in bed, and wrote the school for suggestions." We trust that the school was not away on a holiday. Remember that these extracts are all taken from a socalled medical journal, and not from any "funny sheet." And some members of this cult "treat" hundreds of educated persons, who must be extremely gullible.

In another case report the writer said that the rectum was spastic from "pockets and papillæ," sort of a burlesque pathology. "After fifteen minutes' work, the finger finally passed" into the rectum, and cyanosis and headache disappeared. Too bad that the poor victim did not also disappear toward home and safety.

Another of their astute clinicians reported that a boy after being circumcised—probably instead of getting a new winter suit—became strong and well, and now "could play in the snow." Before, one infers that he could only play in the rain. Just what the prepuce had to do with playing in the snow is a mysterious question. One of them cured a case of constipation by dilating the os uteri; another cured a case of diarrhea by treating the clitoris. (Vol. 7, p. 230.)

These quacks are always optimistic, and at times almost delirious about their method of treatment. For example, one writes, "I never knew where cures came from until I became a student of your course." Another says, "I have been thinking orificially (i. e., of openings) ever since." Still another says, "Doctor, you are the only one out of ten doctors, who ever looked at the foreskin." If a patient should sneeze in the presence of one of these quacks, he undoubtedly would recommend a circumcision immediately.

Another promptly cured a girl of nervousness, stomach trouble and bed wetting by circumcision "combined with dilatation of the urethra and rectum." Another said that he "dilated the internal sphincter, and yet had no reason for doing it, since he could not see anything that looked or felt abnormal." Just to pass the time away, one supposes. Then he adds that he removed a few varicose veins and the patient was able to have an orgasm for the first time in seven years.

It might be interesting here to quote one of the oldest members of this cult in Brooklyn, who with his wife does a very flourishing business. One of them is a homeopath, the other an eclectic; their son is an osteopath. This person took to this form of quackery years ago, when, as he says, "a flood of light burst in upon me." Continuing, he states (vol. 8, p. 68-69), "My first orificial case, a member of my own family (had), baffled the skill of physicians, and for whom I had prescribed silicea, because of the characteristic symptoms of that drug, namely when about to pass a stool, it would slip back. Furthermore, when passed, severe darting pain resembling angina pectoris would pass through the heart."

"Upon reaching home I examined the patient, and discovered three large rectal papillæ. Under local anesthesia I confidently steered my pointed scissors toward their base. To my patient's as well as to may own satisfaction I found that I was at last dealing with a basic principle of cure. The so diagnosed angina pectoris never returned."

"The next year my silicea angina pectoris patient, Dr. ——— (his wife) attended the clinic for orificial surgery with me. She at once became a dynamo of enthusiasm, and proceeded to load our grips with instruments. She could not wait until we reached home to try her hand at orificial surgery. Accordingly, we stopped at ——— Sanitarium in Binghamton, where she cornered me and gave me to understand that I needed the work done; and that I should yield to her wishes." He does not specify whether she operated on his rectum or genitals, nor whether radically or conservatively. "Here were three orificial enthusiasts against me. What could I do?" She said she operated on him wisely "in answer to a great truth from a great truth giver." "With her characteristic expression of something accomplished, she assured me that it had been well done." We trust she did not completely ruin him. But certain it is that more than one woman has been ruined by this lady since. Will one not agree that it is a shame that poor innocent victims are allowed to fall into such hands. It is the son of this pair who announces that he cures deafness and blindness by finger surgery at $15 to $25 a visit to his office. And he does not want for patients.

As I said before, nervous and mental patients particularly, are likely to fall into their hands. In a case where all other doctors had failed, one of them cured a facial neuralgia of eight months' duration, by rectal treatment. Another cured an apoplectic stroke by the same means. Another managed a case of chorea by treatment of the clitoris "combined with deep spinal work over the lower lumbar vertebra." Another explained a case of chorea of five years' duration this way: "Careful examination from an orificial and osteopathic standpoint showed the cause of the chorea was dislocated vertebræ in the cervical and upper dorsal regions, and need of circumcision." He "corrected" these and a cure resulted.

Nearly the whole of the tenth issue of volume 7, of their official "journal" *Constructive Surgery and Medicine,* is taken up with a consideration of dementia præcox. One can imagine how these quacks would handle such a difficult psychological problem. One of them asks, "Can dementia præcox be cured? This question means much if it can be answered in the affirmative, and it is cruel to talk of it, if it must be answered in the negative." Inasmuch as these "doctors" never have any failures, but cure everything by way of the rectum and prepuce, one can readily guess how he answered.

In the discussion on dementia præcox, one of these astute clinicians said, "that you could put a man in bed with one of them, and they would turn their backs on him," thus multiplying the patients while you wait. Another one, discussing this same subject, said that he put a band about a patient's arm, and that the veins dilated greatly: "The idea that veins could dilate that way under excitement, two or three or four times their normal size had never occurred to me. I said, 'This accounts for the thousands of cases of dementia præcox, where he drops from normal to abnormal. He dies and you can't see anything.' " And further we read "that the blood cannot get back to the heart, and we have toxemia." "Toxemia," "autointoxication," and "poison in the system" are favorite catch phrases of theirs.

A defective delinquent girl who had been sick for years, was cured "since her orificial and osteopathic operation had struck the hour of her emancipation." Using meaningless flowery language is a favorite trick of theirs.

One of their number who was handy with the knife reports this "interesting" case. The patient was a demented woman of fifty-six, who became perfectly well and rational the day after the operation, which evidently was sort of a field day affair. This is what she had done to her: "Cæcal readjustment; a subperitoneal fibroid removed; a ventral fixation; circumcised; remnants of hymen and urethral caruncle removed; urethra dilated; the uterus dilated and packed; pockets and papillæ and a hemorrhoid were removed after complete divulsion of the anal sphincters; and to give a new floor to the pelvis, a perineorrhaphy completed the work. . . . This was all done at one sitting, during a rain and hail storm." This last mentioned fact makes the treatment more romantic; and these quacks just flourish by means of romance. We need not comment on the management of this particular patient.

One is not surprised to see that, conforming with the attitude of the ordinary quack, the writings of the members of this cult are full of silly criticisms of legitimate medicine and regular physicians. In fact, in this respect their impertinence knows no bounds. Unwarranted, derisive remarks have always been, and always will be, the weapon of the ignorant weakling, and the fraud.

They say that if regular doctors would only take this brief correspondence course—and no sane physician would so insult his intelligence—that then "the medical world would be . . . much more intelligent, and the poor, defenseless public healthier and happier." Again we read that "orificial thought is so foreign to the medical conception of disease causation, that one will stumble all around it before seeing and appreciating its value." One can conceive that stumbling is one of their chief traits.

They claim to cure conditions "not possible of cure with the general therapeutic measures of the day." They say that the orificial surgeon "is not hidebound, nor is he tied to any hierarchy." No, of course not. We all know that quacks recognize no authority but their own mind, and their mental state is characterized, not by modesty or a desire for the truth, but by impudence and a desire to deceive. Their statement that many thousands of the best American physicians are orificial surgeons is an utter falsehood. Still, why should a quack be limited by the truth.

They also say that "It is surprising that practically none of the famous specialists in the treatment of various organs of the body, including the nervous system, ever examine for orificial lesions. The neglect . . . is appalling . . . they do not see the origin of sympathetic nerve waste." Comment is unnecessary. In their booklet they say, "Orificial application will not interest the lazy doctor." And we might add, "No, nor any real doctor."

Very few doctors, they say, understand the nervous system, but they, of course, are fully conversant with everything about the nervous system, from knowledge which they have acquired from a silly correspondence course devoted to reflections about the rectum and the prepuce! Apparently, they modify the James-Lange theory of the peripheral origin of the emotions and locate the mind in the rectum. For them a single glance at this region is sufficient to diagnose sanity or insanity.

The following from their booklet is characteristically offensive. "Hand this (booklet) to your family physician. If he has taken the postgraduate course, he will wisely advise you." "If he knows nothing (in very large print) of these methods, he is not capable of advising you." All of which means—"Come to us, we only can cure you." And remember that this rectogenital treatment is not only to cure all disease, but to prevent divorce, empty jails, improve one's social status, etc.

If one could for a moment forget the tragedies of this humbuggery, he could not help but laugh at their arrogant nonsense. But these quacks are a real menace to any community. They give some queer titles to the "scientific" articles published in their journal. Here is one, for example, "Live Wires in Male and Female." (Vol. 8, p. 73.)

The following amusing announcement is taken from their "journal." "Orificial cuts for office use." "At the suggestion of . . . the school has made sets of cuts showing different views of normal and abnormal rectum, penis, foreskin, frænum, clitoris, glans, hood, labia minora and vestibule. They are proving to be a valuable aid in case taking. The set will be sent for one dollar." These "cuts," of course, would be very appropriate for a doctor's office. The Metropolitan Museum of Art would possibly be delighted to acquire a set also. For it certainly sounds like a fascinating collection. They advertise that "if generally used, orificial methods would empty our jails, prisons, almshouses, and asylums."

One of the doctors wrote the school that he was most enthusiastic about the course, saying, "If the course gets any better, farther on, I don't know whether I will be able to stand it or not." For the sake of the public weal, let us trust that he could not, and that he has taken up some other business where brawn rather than brains is the *sine qua non*.

The following is evidently written by one of their particularly clever artists: "It was a functional paralysis from orificial impingement (in ordinary English this has no meaning) with complete loss of control of the legs and partial loss of control of the arms. In circumcision, after dividing the dorsal prepuce, the incision was carried to the right. To our surprise the right leg promptly drew up. Then the cut was carried to the left side, and the left leg came up." One is amazed at this wonderful experiment. One trusts the organ was not entirely ruined by this little travelogue. Can anyone but be surprised that these quacks are allowed to live outside of a jail. For there the only thing that they would be allowed to operate on would be a plate of oatmeal.

One of the "doctors" evidently did not fully appreciate one of the correspondence lessons. So he wrote to the school, "I have never seen the ideal prepuce as described in lesson eleven." He then reports the case of a bridegroom who ruptured his short frenum, and as a result of this he became a new man and gained in weight. The doctor called this "an accidental orificial operation." One wonders if the bride *ipso facto* became an honorary member of this cult. Can you imagine a man who has the privilege and honor of putting M. D. after his name publishing this sort of stuff. This "doctor" who never saw the ideal prepuce might have been a success as a song writer. Then we might be singing "Where is my wandering prepuce tonight?" One could hardly imagine, however, with these eagle eyed scouts prowling about that any prepuce would have the temerity to wander far away from home. When it comes to prepuces this cult believes in a massacre.

I was rather surprised in reading one number of their "journal" to find that they had a nose and throat specialist. But I soon discovered that this one practised like the rest of them. I quote from their "journal" (Vol. 8, p. 75): "His special work for some time has been troubles of the upper orifices and cavities, but unlike the usual nose and throat specialist, a large part of his treatment for these troubles is pelvic attention . . . the true spirit of the orificialist." This nose and throat specialist now tells you how to examine the female external genitalia. "Examine the tissue texture as in the male, with the same conclusions in the same existing conditions. If the tissues are full in both labia majora and labia minora, we will have a full blooded person who accomplishes things, provided the tissues in the rectum are in good condition. . . . If the labia majora are flabby or flat, then the round ligaments are relaxed, and we may look for trouble in all the rest of the ligaments." This "professor" should try his hand at writing up the causes of the World War, rectally considered; he ought to be qualified from the submarine standpoint. As a nose and throat specialist, he is certainly exploring territory far from home.

Quoting as I have from their "literature," it has been impossible to avoid a certain monotony in this review. Their ridiculous claims are hardly worthy of any serious study. Yet you would be surprised at the number of educated people who consult them. For none knows better than those scamps that a certain proportion of the public, having no technical knowledge of the causes or the manifestations of illness, are sure to fall into their nets.

The fact that many of these quacks have M. D. after their names makes them doubly dangerous. Others are osteopaths and chiropractors. Like the members of all irregular cults, they are only interested in patients who can pay. The patronage of the poor they do not solicit.

One can hardly believe that any man would subscribe to this fraud. And if ignorance cannot be claimed, then we must say that the members of this cult are arrant frauds. That many of them have certain paranoid trends, and are also actively sadistic, I believe to be true. By assuming the manners and attitude of respectable people, they seem able to deceive the public and the press.

No honest man can ever be a successful quack. The real quack is totally lacking in altruistic feelings and decent traits, yet on occasion can couch his villainy in honeyed language. Some of them even know how to attract champions to their cause. This particular form of quackery is about as low a one as I know of. By means of subterfuge they get the names of prominent people, and use these names to further their ends. They should not be allowed to victimize the poor gullible invalids as they do. But how are you going to stop them? Never by appealing to their decency, for they have none.

Louis Pasteur

By LOUIS GERSHENFELD, Ph.M., B.Sc., P.D.,
Philadelphia,
Professor of Bacteriology and Hygiene, Philadelphia College of Pharmacy and Science.

Louis Pasteur was the most striking figure in nineteenth century science. He revolutionized chemistry, physics, biology, medicine and surgery, and opened up new fields in bacteriology and sanitation. His work on practical subjects, on fermentation and spontaneous generation, not only represent great advances in science but opened new avenues into scientific knowledge.

Louis Pasteur was born on December 27, 1822, at Dole, France, the only son in a family of four children. When young, his family moved to Arbois, where he attended the Arbois primary school and later the College of Arbois. He was merely an average student, showing a marked taste for drawing. In the fall of 1838 Pasteur went to Paris to attend a boarding school but was soon compelled to return home because, as he expressed it, of the loneliness in Paris. He again entered the College of Arbois and during 1839 carried off many prizes. Because the classes here were not far advanced, the following year he went to the Royal College at Besancon. Here he taught physics and mathematics, receiving board, lodging and a small retaining fee. He successfully passed his examination in the studies he pursued at the Royal College and in 1842 took an examination to gain admittance into the Ecole Normale. Dissatisfied with the low average he received in his entrance examination, he resigned and decided to compete again the following year. During the interim, he gave private lessons in mathematics and attended lectures on chemistry by J. B. Dumas, the great chemist. At the end of the year he took his admittance examinations again and was fourth in the list for the Ecole Normale. Here he proved to be a satisfactory pupil but did not distinguish himself by any exceptional merit. From 1844 to 1847 he was devoted to the study of chemistry. During the first five months of the year 1848, four different papers were presented by Pasteur to the Academy of Science on the subject of crystallography. In the same year he was made professor of physics at Dijon. In the month of January, 1849, he was appointed to the chair of chemistry at Strassburg. It was here he met the daughter of the rector of the academy whom he married during the month of May of the same year. For the next few years, until 1853, he followed up researches in crystallography and during May of the latter year he succeeded in transforming tartaric acid into paratartaric acid.

He proved there existed various forms of tartaric acid—all identical from the point of view of their physical and chemical properties, save that they each had their special hemihedral facets and the corresponding rotary power. The first effect was that of gaining for Pasteur the Cross of Chevalier of the Legion of Honor and a prize of 1,500 francs awarded by the Pharmaceutical Society of Paris. His growing reputation led to his nomination in the fall of 1854 as professor and dean of the newly created Faculty of Science at Lille.

His next great study was an attempt to explain to his satisfaction a correct reason for fermentation. It was in his writings on lactic acid fermentation, published in 1858, that Pasteur presented the idea that a specific ferment was associated with each fermentation. He further mentioned that if two organisms simultaneously invaded the same medium, the one which was best adapted to the existing conditions continued to flourish and produce the characteristic end products.

It was during the beginning of these studies on fermentation that he accepted the nomination of administrator of the school and subdirector of science studies at the Ecole Normale in Paris. It was here he arranged for a small laboratory at his own expense and where he followed up his investigations on alcoholic fermentation.

In 1860 he published his thesis on alcoholic fermentation, in which he pointed out clearly that glycerine and succinic acid were formed in considerable quantities and almost as constantly as the principal products of the fermentation. After thorough work on alcoholic fermentation which proved the truth of his theoretical assumptions, he returned to lactic fermentation and started other experiments along these lines. A distinct surprise was, however, in store when he experimented and was able to produce a butyric fermentation. Bodies similar to the nonmotile alcoholic and lactic ferments (which were considered as vegetables) were not present. The butyric ferment he first called vibrios and because of their motile nature regarded them as of animal origin. Little did he suspect that this discovery would soon open a new world, the kingdom of the bacteria. Another important fact that he observed was that the butyric vibrio lives in the absence of oxygen and in fact fears its contact, thus the introduction of the idea of anaerobic life.

In all his works and writings on fermentation he presents the problem in such a clear way as to prove definitely that fermentation is a specific phenomena, due to the existence and development of a particular organism specific for each different type of fermentation. After demonstrating that ferments cause fermentation, Pasteur proceeded to prove definitely to the partisans of spontaneous generation the germ theory. He definitely and convincingly showed the existence of living organisms in the air. He even determined the temperature necessary for their destruction and pointed out the necessity of flaming all receptacles used in microbiology—a technic still in vogue today.

It was during his experiments on microorganisms in the air that he mentioned in his communications to the Academy of Science the use of cotton as a filtering agent to remove bacteria, the advisability of heating milk to 110° C. or 112° C., or one and a half atmospheres, to kill all the germs, and if their reinvasion is prevented no alteration will occur; thus the introduction of steam under pressure, or the autoclave. He made mention of the existence of germs that produce spores as the Bacillus subtilis, and showed that boiling at 100° C. was not sufficient to destroy this organism but that it must be submitted for a half hour in an autoclave to a temperature of 120° C. He even stated that blood, urine and body fluids most prone to alteration, if removed with suitable precautions from normal healthy living animals, could be kept without alteration, provided the air in the immediate environment was freed from germs, and finally he clearly demonstrated that the dust in the air contained the germs, and the more dust laden the air the more numerous the germs. It was in the latter communication that he showed the direction of his thoughts when he said: "It is very desirable to carry these researches sufficiently far to prepare the way for a serious inquiry into the origin of disease."

In 1861 the chemistry section of the Academy of Science awarded him a prize. In 1862, after his third attempt, he was nominated member of the Academy in the section of mineralogy.

Pasteur showed clearly that the socalled diseases in wine, etc., that is, bitterness, acid taste, ropiness, were due to the presence of foreign germs and he set about and showed how to correct these faults. The practical consequences of his discoveries equalled their theoretical promise.

He soon interested himself in the changes in alcoholic liquids which led to the formation of vinegar. His experiments and observations, which were announced in two communications to the Academy of Science in 1862 and in an article in the scientific annals of the Ecole Normale in 1864, started one of his greatest discussions and conflicts with Liebig, the eminent German chemist.

Pasteur gave conclusive proof that what was necessary was the Mycoderma aceti. This organism he proved to be singularly prolific, and possessed of a marked aerobic character. It was here with the collaboration of Chassang, professor of Greek, that the word aerobic was coined, and to characterize the opposite function, as in the vibrio butyricus, the word anaerobic. This aceti microorganism takes the oxygen from the air and transmits it to the alcohol for oxidation. In 1867, at the invitation of the mayor and the president of the Chamber of Commerce of Orleans, Pasteur went there and taught his method to the manufacturers in that town. He restored security to the Orleans vinegar manufacturers, who could control and regulate the production, and thereafter succeeded in making rapid progress.

Pasteur now reached one of the turning points of his life. For a long time he seemed to connect the theories of fermentation with those of disease and this relationship became still closer when he convincingly proved that living cells controlled the processes of fermentation. It seemed, as was pointed out in many writings by his associates, that Pasteur hesitated coming in contact with diseased conditions in the higher animals, because he always asserted that he was not a physiologist, though he did attend a course of lectures given by Professor Claude Bernard.

In the early part of 1865, Pasteur was compelled to take up the problem he had hesitated over for so long a period. He had been asked to take up the study of the silkworm disease, and with great hesitation he finally accepted the mission offered to him. He had only the vaguest idea of agriculture. He, however, soon acquired a fragmentary knowledge of the general structure of the larvæ of insects by causing the latter to be dissected in his presence, and obtained as much information as he could from the latest published works on the subject. In June, 1865, Pasteur set out for the silkworm district of France. His researches lasted for six years. Pasteur showed that the failure of the silkworm was due to two diseases, *pébrine* and *flacherie,* which were directly communicated to the eggs of the worm. To prevent the disease it was necessary to procure absolutely healthy eggs and then prevent their contamination by diseased worms. The eggs of worms which showed signs of disease were to be rejected. Pasteur thus discovered the cause and course of the disease and presented the foregoing simple suggestions as a method of preventing its recurrence. By the introduction of these precautions, the silk industry of France was brought back to prosperity.

The six years which he spent in studying the silkworm disease were the hardest days of his life. Fate had dealt him a number of blows which had made his work doubly difficult. He had already lost his mother and his eldest daughter. At the outset of his work in June, 1865, he was summoned to his dying father and arrived only in time to attend the funeral. In the month of September, of the same year, he lost his youngest daughter, Camille, who was barely two years old, and in May, 1866, his daughter, Cecile, died at the age of twelve and a half years. Of the five children who had been an inspiration to him, only two remained.

On July 1, 1867, he was summoned to Paris where he received a prize awarded to him for his studies on wine. During this period there were some disturbances that occurred at the Ecole Normale. The school was reorganized. A complete change of faculty took place and Pasteur was compelled to drop out. He, however, was soon appointed professor of chemistry at the Sorbonne. In April of 1868 he saw to his great joy the beginning of the building of the laboratory of chemical physiology, as he termed it. The strain of work and the worry of all the controversies Pasteur had at this time was too great, and in October of 1868 he was seized with apoplexy. (It seemed that even fate was against him.) He could not speak and his left side was paralyzed. His convalescence was slow but steadily progressive, and it was not until the early part of 1869 that he was able to get about. He never completely recovered from this illness and was always afterwards somewhat lame.

A few days after Pasteur had left Germany in July, 1870, where he stopped to visit Liebig, war was declared. His son, aged eighteen, soon enlisted, and Pasteur with his wife and daughter withdrew to his old home at Arbois. He was so highly incensed at the outrages committed, that in January, 1871, he returned to the dean of the faculty at Bonn the diploma of doctor of medicine which had been awarded him in 1868 by the university of that town in recognition of his work. During this period he refused an offer by some Italians for a directorship of a laboratory in Milan or a chair of chemistry at Pisa. From 1871 to 1876 Pasteur did considerable work in improving French brewing. In 1873 he was elected a member of the Academy of Medicine in the section of free associates.

Ideas about infection were confused, and more or less opposition was encountered against the attempt of connecting Pasteur's ideas respecting fermentation with that of diseased conditions. About this time Pasteur began to read more and more of the works of men in medicine, surgery and allied sciences. He seemed to be especially interested in the studies which Davaine was pursuing upon anthrax. In 1861, Davaine proved definitely to the satisfaction of all that a rod shaped organism, which he called a bacteridium, was the cause and the sole cause of anthrax. In 1877, Pasteur with the collaboration of Jobert made his first experiments on anthrax. It is interesting to point out here as mentioned by Duclau, that, Pasteur being neither a physician nor a veterinary surgeon, the history of any disease as a disease did not interest him. What he studied was not so much the anthrax disease as the anthrax bacteridium. He had at his command the method of obtaining pure cultures and thus he had the big secret in being able to study the physiological properties of organisms, to compare them in their pathological reaction, and to establish definitely the etiology of a disease.

During 1870 to 1880 he devoted much time to the study of anthrax, even traveling through infected districts. In his conclusions he mentioned the many peculiar characteristics of the anthrax bacteridium. He showed that a number of diseases existing under different names in animals were nothing more than one and the same disease—anthrax. He even demonstrated that the carcasses of animals might aid in the distribution of the disease if they are not buried deeply below the surface of the ground. It is also here that Pasteur introduced the first example of what was to be called bacteriotherapy.

Some observers in inoculating animals with putrid anthrax blood found that death was quickly produced with symptoms similar to anthrax, but bacteridia were not found in the blood. Pasteur set out to study this condition. His investigation immediately revealed a number of important facts. He clearly showed that the condition which developed was a different disease. The latter was caused by a common bacillus which he calls the vibrion septique. This is known today as the bacillus of malignant edema. He showed that the period of incubation was shorter and death resulted more quickly. He made haste to study the physiological characteristics of the organisms and immediately pointed out that it was an obligate anaerobe and a marked gas producer.

Mention should be made at this time of his celebrated lecture delivered at the Academy of Medicine on April 30, 1878. In his own name, and that of his collaborators, Jobert and Chamberland, he elaborated his germ theory and its application to medicine and surgery. In the suggestions of Pasteur one can constantly foresee the aseptic method.

Pasteur carried on the researches which dealt with facts pertaining to human pathology. In 1879 he examined pus from boils and showed the presence of a microbe which he was able to cultivate. The latter appeared microscopically as a mass of rounded granules comparable to irregular bunches of grapes; hence the name staphylococcus which it received. He shortly proved this same organism as the cause of osteomyelitis.

At about this time considerable discussion had begun at the Academy of Medicine on puerperal septicemia. Pasteur examined discharges and secretions from such infections, and he found in all instances the presence of a microbe which had the appearance of strings of beads (the organism known today as the streptococcus). He had no hesitation in declaring this organism to be the commonest cause of infection in women after delivery. In one of these discussions Pasteur declared it was the doctor and his assistants who carried the microbe from a sick woman to a healthy one.

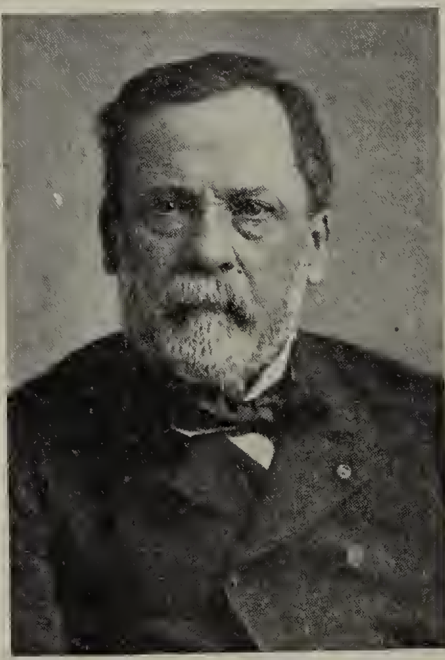
The year of 1880 was a strenuous one. In April he wrote an article on the bacterial nature of plague; in October he read an address at the Academy of Medicine on vaccinia and variola; and in December he began his work on rabies, but his greatest success during the year was his work on chicken cholera. Pasteur succeeded in finding the germ which was the cause of this disease, first observed in 1869 by Moritz, a veterinary surgeon. This germ was successfully cultivated on artificial culture media and always produced the characteristic disease when inoculated into fowls. The course of his experiments were interrupted by a period of vacation. On his return he was annoyed when it was found that these cultures failed to produce the typical symptoms of the disease, when injected into the fowl. To his surprise, the inoculations instead of proving fatal produced but slight symptoms, and the fowls shortly thereafter recovered. After some trouble Pasteur procured fresh cultures of the chicken cholera organisms. Fresh fowls when injected with the latter soon died, exhibiting all the characteristic symptoms of chicken cholera. But when these fresh cultures were injected into fowls which had previously been inoculated with the long standing cultures, no characteristic symptoms were produced. It seemed that those fowls that suffered from the mild form of the disease produced by the old culture were protected from further attacks of the disease.

One of the great mysteries of medicine had thus been revealed. The attenuation of a virulent microorganism, that is, the loss of its disease inciting power, had been attained by the increased age of the culture. He immediately began to apply practically his new theory by providing old cultures for the inoculation of fowls in districts where chicken cholera produced serious ravages.

Mention was made previously that Pasteur was at intervals working on anthrax. With renewed enthusiasm he proceeded to produce a vaccine material for anthrax. His method of attenuating this organism consisted in exposing the cultures of the organism for various lengths of time over a period of successive days at a temperature slightly higher than the maximum temperature at which the organism will grow. After many difficulties and a number of investigations Pasteur succeeded in immunizing sheep and other animals against anthrax. The Society of Agriculture of Melinn had proposed to Pasteur a public trial of this new method. It was in May, 1881, that Pasteur gave this public demonstration, and conclusively established the value of anthrax vaccination. In August of 1881 Pasteur attended the International Medical Congress in London and in December the same year he was elected a member of the Academic Francaise.

From anthrax Pasteur went on to the study of swine erysipelas, rouget, swine fever, or red disease of pigs as it is at times known. One of Pasteur's collaborators, Thuillier, isolated the causative agent, and within a few years Pasteur had established a method of protective treatment. At about this time Pasteur began to receive many medals from different societies and communities who wished to show their gratitude to him. In 1883 the national recompense which was awarded to Pasteur in 1874 was raised from twelve thousand to twenty-five thousand francs. On July 14th, of the same year, he was invited to be present at the placing of a commemorative tablet on the house in which he was born at Dole.

The government offered Pasteur the Grand Cross of the Legion of Honor in lieu of his great discovery of splenic fever and anthrax vaccination. This he condescended to accept only after one condition was met, and that was an award of the red ribbon or cross for his two collaborators—Chamberland and Roux.



LOUIS PASTEUR

While the various researches were being closely watched by Pasteur, one study seemed to be placed above all others. This was his work on hydrophobia or rabies, which he undertook in December, 1880. He soon became convinced that the infection has its seat in the nervous system, and particularly in the medulla oblongata. While working along these lines, he examined the saliva of those who had died of rabies, and succeeded in obtaining an organism from one of these cases in the early part of December, 1880. Following up the study of this new organism he found it in the saliva of people who had died of disease as well as in the saliva of normal healthy individuals. He soon, thereafter, came to the conclusion that this organism, as well as the disease which it produced, had no connection with rabies. It was the same organism which Sternberg in this country reported the same year. A few years later it had received the name of pneumococcus after Frankel who demonstrated its presence in the lungs of persons who had died of pneumonia.

Pasteur therefore was compelled to use the medulla oblongata as he felt assured the causative agent of rabies was confined to this tissue. By means of the latter he successfully produced typical rabies in other animals. Unable to establish definitely the specific causative agent he continued his researches with the idea of attenuating this virus and established a method of prophylaxis. By a series of passages of virus from rabbit to rabbit he finally succeeded in obtaining a uniform virus which possessed a fixed virulence producing rabies after only a one week period of incubation. Further passage from animal to animal did not tend to further reduction of the incubation period. His method of attenuation in this instance consisted of suspending the cords (specifically of fixed virulency therefore known as virus fixe) in a series of flasks at the bottom of which there were placed several pieces of potash. He found that the longer the period of time in which the cord remained suspended the less virulency did the particular cord possess, and finally if exposed for a period of fifteen days all virulency seemed to have disappeared. His method of inoculating humans with these cords, starting with those that possessed slight virulency and increasing not only the dose but also the use of more virulent cords, was soon introduced. Most all countries and many of the governments after careful investigations officially recognized the value of the Pasteur treatment as it became and is still known today, and introduced it in their respective countries. Pasteur institutes sprung up all over the world in many of the leading countries and Pasteur lived to see the crowning of his work on rabies when in November, 1888, the Pasteur Institute in Paris was opened.

In 1884 Pasteur had represented France at the International Medical Congress at Copenhagen, Denmark. The enthusiastic demonstrations which took place in his honor were numerous.

When the Pasteur Institute was finally completed, due to the hearty support of both rich and poor in subscribing to the building fund, he moved his quarters to the institute. He, however, was ill and weary. He attended the hydrophobia clinic almost daily, and superintended the production of the vaccine material. At the same time he was constantly offering suggestions to his assistants, especially Dr. Roux and Dr. Yersin, who were pursuing the study of diphtheria. Later when Dr. Yersin began his wonderful work in Asia working in areas in which bubonic plague was epidemic, Pasteur followed with great interest the communications sent to the annals of the Pasteur Institute. It was Yersin who discovered the causative agent of the bubonic plague.

On December 27, 1892, one of the greatest receptions ever given any living man took place in France. Many men from all walks of life made speeches and presented addresses. It would be impossible to attempt to mention even some of the important ones but a few of the remarks with which Lister greeted Pasteur are of interest: "Truly there does not exist in the whole world an individual to whom medical science owes more than to you." "Your researches on fermentation threw a powerful light which has illuminated the dark places in surgery and has changed the treatment of wounds from an uncertain, empiric and too often disastrous business into a scientific and certainly beneficial art. Thanks to you, surgery has undergone a complete revolution which has deprived it of all its terrors and which has increased its efficacy to an almost unlimited extent."

It was in September, 1895, as Pasteur's career was coming to its close, that he saw about him the entire routine of the making of diphtheria antitoxin, the discovery of which was announced the year before.

On Saturday, September 28, 1895, at 4:40 in the afternoon, Pasteur passed away very peacefully. His ashes repose in a beautiful chapel situated below the main entrance a little lower than the ground floor of the Pasteur Institute. The walls of the chapel are inscribed with the scientific triumphs of the master whose ashes repose there. It is a striking array of headings, representing a great step forward in science. His devoted wife died September 24, 1910.

Pasteur was constantly encountering critics and enemies, who at times made his life unbearable, but with the high quality of thought which constantly guided him he always outflanked these obstacles. Unlike the generality of great men, he, however, enjoyed the meed of almost unstinted appreciation during life. He looked upon the cult of great men as the great principle in national education and he constantly advised students to worship great men. He was always irritated when scientists, involved in arguments over their problems, brought in for consideration the question of nationality. It was at a banquet at the close of the International Congress on Sericulture held at Milan that Pasteur pronounced the words so often repeated: "Science has no country but the scientist has one." In his Lille speech, the sentence "in the fields of observation, chance only favors the mind which is prepared" was particularly applicable to him.

There are many examples of Pasteur's insight, his ability to discover and state a problem, of the patience with which he gathered together information. He lived in advance of his time. He lived with his thoughts without being a dreamer for his dream so regarded at the beginning eventually bore fruit.

It was therefore fitting that scientists the world over united to honor this genius on the centenary of his birth, he whose work had proven of such great and practical utility for mankind and whose knowledge and discoveries are even today beginning their career of developing suggestions and thoughts to scientists.

1831 Chestnut Street.

Pasteur's First Patient

By MALFORD W. THEWLIS, M.D.

Providence, R. I.

The centenary of Pasteur brings to mind events of the scientist's early life—a life of sacrifices and endless toil. The story of his first patient is well known as given by several biographers, yet it might be interesting to hear it exactly as it was told by the patient himself.

Joseph Meister, the first patient of Pasteur, is now janitor of the Pasteur Institute. He is an Alsatian, the son of a baker and pastry cook in the town of Sénesthal. On July 8, 1885, the elder Meister sent his son, then nine years old, to the next town to get some yeast. He left at about five in the morning with a tin pail in hand. At the corner of the street a gigantic dog rushed at him and cruelly bit his hand (he still shows his scar). He fell back on the sidewalk, the dog continued to attack the boy and inflicted not less than fourteen wounds on his legs. As he was crying for help a blacksmith ran toward him and with an iron bar stunned the animal. When the boy was picked up he could hardly stand. Several hours later his mother took him in a coach to the nearest doctor to have the wound dressed.

The autopsy of the dog had been made and hydrophobia recognized. His mother was extremely worried. At this time Pasteur's experiments on hydrophobia were hardly known. It was only the next day that the newspapers told of the experiments which had been attempted by a chemist in Paris (Pasteur) and these had been successful.

The mother was brave, she realized that her only chance for her boy would be to go to Paris and find the scientist mentioned. The next day they went to Paris by train, where they were among strangers, finding themselves confronted with difficulties. In all the hospitals they visited they were invariably told that the address of Pasteur was not known and that his experiments on hydrophobia were not as satisfactory as the newspapers had heralded. The seeds of professional jealousy had already been sown. They went from one hospital to another in vain until they came across someone who happened to know where Pasteur lived and his address was given to them.

However, Pasteur, when found, did not seem willing to treat the child. The boy's mother begged him to treat her son; Pasteur replied to the woman that thus far his experiments had only been performed on animals, and that they might be dangerous to man. She pleaded and Pasteur's great heart overcame his moral scruples, the mother told him that he alone could save the child and if necessary she would make the sacrifice of his life, to her it was to be immediate death or salvation, instead of the ghastly end she dreaded.

Touched by her prayer and confidence, he immediately gave the child his first inoculation and the treatment lasted twenty-one days; at the end of a month the boy returned to his parents completely cured.

Pasteur continued to inquire about Meister's health and the latter wrote to Pasteur every other day for a long time. The scientist treated the boy as if he were his own son, later he gave him the position he still holds as janitor.

The poor man's devotion to his savior's memory, its touching simplicity, is as great a tribute to Pasteur as the elaborate monuments erected by scientific bodies who had misunderstood and ignored him during his years of struggle.

193 Watermann Street.

Editorial Articles

FREUD ON HAMLET.

The recent popular interest in John Barrymore's masterly interpretation of *Hamlet* makes it especially worth while to recall Freud's conception of the same character, upon which Mr. Barrymore undoubtedly based his representation of the Prince of Denmark. In his great work on *The Interpretation of Dreams,* Freud places Shakespeare's *Tragedy of Hamlet* on a level with Sophocles's *Œdipus Tyrannus,* as the greatest creations of tragic poetry based on the theme of the infantile incest wish. The wide difference in the two dramas lies in the difference in the psychic life of the two widely separated periods of civilization —"the agelong progress of repression in the emotional life of humanity is made manifest in the changed treatment of the identical material." In *Hamlet,* the basic wish phantasy of the child, instead of being brought to light and realized as in a dream—that which happens in *Œdipus*—remains repressed, and its existence is revealed, like that of a neurosis, only by the inhibition resulting from it. Up to the present time Goethe's explanation of Hamlet's vacillations and hesitations has been the generally accepted one—that he was the type of person whose energies were paralyzed by an overdeveloped intellect—"sicklied o'er with the pale cast of thought." Others interpreted him as a weak, morbid neurasthenic, on the verge of insanity.

Freud points out, however, that Hamlet is not represented in the play as a man wholly incapable of acting, citing his killing of the eavesdropper Polonius, and the cunning plan of sending the two courtiers to death as illustrations of his point. This leads us to the conclusion that there must be some special reason why Hamlet is unable to avenge his father's death. Freud writes: "Hamlet can do everything but take vengeance upon the man who has put his father out of the way, and has taken his father's place with his mother—upon the man who shows him the realization of his repressed childhood wishes. The loathing which ought to drive him to revenge is thus replaced in him by selfreproaches, by conscientious scruples, which represent to him that he himself is no better than the murderer whom he is to punish." Freud goes on to explain the unconscious character of this mental content, and quotes the conversations of the prince with Ophelia as showing the sexual disinclination consequent upon his state of mind.

Mr. Barrymore sacrificed some of the analytical interest of Shakespeare's representation by cutting a good deal of the closet scene between the queen mother and Hamlet in Act III, no doubt out of deference to the standards of modern audiences, to whom the gross frankness of Elizabethan speech is offensive. The interested student, upon reading this scene, can hardly fail to be convinced of the grounds of Freud's interpretation.

Dr. Ernest Jones, of London, and Dr. Otto Rank have contributed to psychoanalytical literature interesting essays confirming Freud's theory of Shakespeare's great tragedy.

THERAPEUTIC ACTION OF IODINE.

Iodine is the specific medicament for lymphatic tissue whose hyperactivity it induces, namely, hyperactivity of the lymph nodes and spleen (so important in the treatment of scrofula and lymphatism), mononuclear leucocytosis in the blood of a persistent nature and differing from the polynucleosis produced by nucleinic acid. Finally, iodine is a microbicide, an antitoxic, and a destroyer of bacterial poison; it reinforces the natural agents of organic defence, hence increasing vital resistance.

Iodine possesses a stimulating action on the processes of disassimilation. When absorbed the drug divides into two parts, one being eliminated in the urine in the form of sodium iodide, the other combining with the proteins of the blood serum and giving rise to iodoalbumins, being rapidly fixed by the leucocytes which convey the iodine to the thyroid gland, lymph nodes and spleen. The albuminoid molecule is thus rendered more easily and more completely oxidizable; and still more the drug produces a transudation of the lymph into the lymphatic spaces and the resulting hydremia produces a true drainage of the tissues, relieving the cells of the waste product of nutrition, a fact which explains their possible recovery, as for example in asthma.

This lymphagogue action of iodine must be treated with respect and it should be borne in mind that it is above all marked in the iodides and that in infected or anemic subjects and thin individuals, iodine, even in small doses may increase the emaciation by its action on fat and the albumins. On the contrary, pure iodine possesses an intense hemopoietic and antiseptic power and a weak lymphagogue action.

Iodine increases the respiratory quotient, increases the activity of the pulmonary circulation, facilitates expectoration, thus disencumbering the bronchi, and hence relieving the patient's asphyxia. The drug is a basal dilator, regulates the work of the heart and lowers the blood pressure. It possesses a stimulating action on the thyroid, suprarenals and hypophysis.

Toxic phenomena occur only with the iodides. As to accidents of true iodism resulting from pure iodine, colloidal iodine, or the organic iodine compounds, it may be said that practically they are nonexistent. The accidents due to iodism are of a hyperemic nature and are the result of a brutal play of the lymphagogue power of the drug; they consist of oculonasal catarrh, bronchial catarrh, dryness of the throat, salivation, edema of the glottis, acne, and erythemata. The drug follows secondary routes of elimination, namely, the laryngeal, pharyngeal and bronchial mucosæ, the tears, saliva and sweat, and the principal way of elimination is by the urine.

These data permit of two conclusions, first, the multiple and energetic action of iodine, and second, the serious inconveniences resulting from the exhibition of the iodides. Hence the necessity of prescribing a chemically definite product, the best of all being an iodoorganic one, as these are well supported by the digestive apparatus and are practically devoid of any untoward effects if exhibited with all due care.

THE AGE OF UNREASON IN THE CULTS.

With respect to correct and proper teaching of public health matters, the irregular practitioners have fallen upon evil days. For many years regular medicine has been trying to educate the public in those matters which influence the prevention of disease and the prolongation of life and it has succeeded in some measure; but now there seems to be an overwhelming flood of misinformation and ill timed advice coming from sources which are wilfully perverting the truth. First, there are the osteopaths who are throwing science and reason to the winds and insisting that every disease can be cured by manipulation. The chiropractors are doing about the same thing and in some quarters there is a pretty quarrel on as to whether the osteopaths have learned their art (?) from the chiropractors or vice versa. But they are ably seconded by the Christian Scientists who even go one step further in denying the very existence of disease, yet they do not hesitate to attempt to heal by prayer that which does not exist.

The latest of the irrationalists is the exalted pharmacist, Dr. Coué recently in America, who has come forward with an age long theory that all disease can be suggested out of the mental sphere through selfhypnotism. The gullible public is taking this and other socalled teachings very much to heart, but of course, one need not be alarmed that any of these will persist throughout the ages; for it is a matter of common knowledge that most false doctrines have fallen by the wayside, and whatever good there is in any of them has long since become a part of the great science and art of medicine. The real harm that the followers of these cults do is their false teaching, and one may truly say that what they *do* is not nearly as bad as what they *say*. To deny the efficacy of vaccination; to attempt to pass laws which will forever hamper and prevent vivisection; to deny the germ theory of disease, and to refuse the succor of morphine in alleviating pain —all of these are bad in that they make it more difficult for scientific medicine to proceed with the great tasks she has set herself.

Recently a magazine, devoted to the interests of a health cult, ran a full page advertisement in several of the great metropolitan dailies. This advertisement was particularly ridiculous in that it stated that one could determine the day of his death, or, in its own phrasing, that "you can decide now when you will die." It goes on to say that fate does not set the date but, "We humans do that ourselves, depending upon the care we give this flesh and blood mechanism we call the body." Then there are cited feature articles to which especial attention is called, the first of which is Foods For Easy Maternity. This states that "If a woman will eat the proper kind of food there will be neither pain nor peril to childbirth." In other words, the accidents of gestation are not to be considered. To the writer of this "stuff," there is no contracted pelvis, no placenta prævia, and no infections of the genital tract. That, of course, is very ideal and much to be hoped for, but does not and never will exist, possibly even among angels. Another article has the caption Stop That First Sneeze. This intimates that hay fever is due to a lack of selfcontrol and that if one will suppress the first sneeze a cure can be effected. It mentions the case of a woman cured by this method. It has no interest in the pollen origin of hay fever or in anaphylaxis or the theory of the internal secretions as possible causes of this symptom complex.

Still another article that is even more pernicious states that Cancer Can Be Cured By a Cleansing Diet. This goes on to describe the case of a woman, "the lower half of whose stomach and intestines were a mass of cancerous tissue," but who is now in excellent health through eating the proper food. Unfortunately, some credence might seem to have been given this pronouncement by certain medical authors who have appeared in the lay press as advocating dietary treatment instead of surgical operation for the cure of cancer. The fallacy of diet as a cureall has been carefully nurtured by the osteopaths and chiropractors, especially in regard to the kind of bread one eats. One woman chiropractor with whom we are acquainted, makes bread and sells it to her patients and advises them never to eat any other kind if they would be well. This only shows to what extent the faddists will go and how very dangerous promulgation of their imaginings becomes, when, as we all know, anything that postpones early diagnosis and immediate surgical procedure means fatal procrastination in most cases. There are thousands of people who, whenever they read such "stuff," are eager to grasp at the floating straw, and who, if they are not destroyed by the folly of their own credulity, may spread a kind of untruth that will poison hundreds of minds against correct scientific teaching.

Akin to this sort of thing are the fancies of those singing teachers who tell their pupils that through some special method of breathing they can "inhale health," and never catch cold. It is, of course, just as reasonable to assume that one will never be hit by an automobile as to say that an acute infection of the airways can never take place if one breathes thus and so. Even the hardiest and most rugged individuals sometimes become infected with socalled colds and influenza, and in the epidemic some years ago many of the victims were strong, out of door individuals who had never been sick before, but who quickly succumbed.

Public safety can only be safeguarded by contradicting this information, by "scotching" it wherever it shows its ugly head, and by supplanting it with information which is absolutely accurate. It is not enough to talk excitedly at medical meetings or even to write in a lukewarm and general way, but wherever a specific instance is known, such as the flagrant one herein cited, we should immediately train our guns on that position and fight fire with fire.

ANNUAL REPORT OF THE UNITED STATES PUBLIC HEALTH SERVICE.

The Public Health Service of the United States has recently issued its fifty-first annual report, covering the one hundred and twenty-fourth year of its existence. The subject matter of the report is grouped according to the work of the seven divisions under which the bureau is operated. These are the divisions of scientific research, of domestic quarantine, of foreign and insular quarantine and immigration, of sanitary reports and statistics, of marine hospitals and relief, of personnel and accounts, and of venereal diseases. The year covered in this report, ending June 30, 1922, was eventful from a service viewpoint for two reasons—the increasing resumption of public health work, and the relinquishment of certain functions previously performed in relation to the care and treatment of exservice men and women. One of the scientific accomplishments of the year was the development of a new gas for the fumigation of vessels for the purpose of destroying disease bearing insects and vermin. Experimentation has indicated that it is effective, and that it can be applied with safety, and without damage to vessel or cargo.

The transference to the Veterans' Bureau of many of the activities relating to the medical care and treatment of veterans of the World War has greatly decreased the facilities and personnel of the service. On June 30, 1921, the total personnel of the Public Health Service was 23,078; on June 30, 1922, it was 9,357.

The policy of cooperating with other governmental agencies, both domestic and foreign, in public health activities has been continued. One feature of the extension of the permanent hospital facilities has been the establishment of a radio service for the relief of the sick on vessels at sea, and in broadcasting public health information.

An interesting fact shown by the report is that the development of rural sanitation has proved to be one of the most economical activities of the service from the viewpoint of measurable returns. Special studies have been made of industrial hygiene, stream pollution, disposal of human wastes, and certain endemic diseases, among them amebiasis, botulism, gonorrhea, leprosy, malaria, meningitis, pellagra, pneumonia, Rocky Mountain spotted fever, tuberculosis, trachoma, tularæmia, typhoid fever, and syphilis. Measures for venereal disease prevention have been proved so valuable and necessary that they will eventually be placed on a permanent basis in all the States. A series of public health institutes were held in a number of the larger cities of the country, and a conference on the future of public health in the United States and the education of sanitarians in Washington.

Prevention and quarantine of epidemic diseases was particularly successful during 1922, shown by the fact that, with the exception of localized outbreaks, there was an absence of such diseases during the year. Bubonic plague is perhaps the most widespread of all diseases of a pestilential character in the world, except smallpox. In 1921 this disease threatened to become partly epidemic in the South, but prompt and radical measures were applied to local conditions and served to prevent its spread. Yellow fever foci were reported in Mexico, Central America, and the coast cities of South America, but, in spite of the fact that close and active commercial relations were kept up with these countries, only five cases of fever reached domestic ports, and the disease was excluded. The same was true of cholera, smallpox, and typhus fever, so prevalent as an aftermath of the war in European countries. This was accomplished in part by the stationing abroad of trained officers of the service to help enforce the quarantine laws and regulations. All maritime quarantine stations at domestic ports are operated by the service, and all arriving aliens are examined. The opening of a new hospital for lepers has inaugurated the segregation of lepers in the United States.

WORKMEN'S COMPENSATION INSURANCE.

An interesting bulletin comparing the various forms of workmen's compensation insurance and their administration in the United States has recently been issued by the Bureau of Labor Statistics, Washington. Carl Hookstadt is the compiler of the bulletin. In 1919 the Bureau began an investigation of compensation insurance systems, the points upon which information was particularly sought being relative costs, security, and service of the various types of insurance carriers. Also, a study was made of the administrative procedure of State industrial commissions and funds, especially as regards accident reporting and claim procedure. A description of the claim procedure methods in each State is given. The investigation covers twenty States and two Canadian provinces.

A brief summary of conclusions is of interest. As to cost, it was found that under an exclusive State fund the cost to employers would be thirty per cent. less than under stock insurance and sixteen per cent. less than under mutual insurance. The total saving to insured employers of the United States, if all were insured in exclusive State funds, would be over thirty million dollars annually. Comparisons of service were difficult because of the great variation among insurance systems. As to promptness there was little to choose among the different types of insurance carriers. Most of the State funds were found to be more liberal than either stock or mutual companies. Some private companies are doing excellent safety work, but few of the States have done any effective work of this kind. As to security, so far no injured workman has lost his compensation because of the insolvency of State insurance funds, nor has any large mutual company become insolvent. Twenty-one States reported on self insurance; in fifteen of these no self insured employer has failed or gone into the hands of a receiver. Four systems of claim procedure are in use in the various compensation States. These are claim system, voluntary agreement or direct settlement system, adjudication of cases on basis of employer's and insurer's reports only, and hearing system. An accurate appraisal of the foregoing systems was difficult to make for methods of reporting results and factors entering into reports vary so widely. The claim system is used in nearly all State funds and by two or three commissions. Agreement systems were found in a majority of the commissions and in several funds. Several States have adjudication of claims on the basis of employer's and insurer's reports only. The merits of this system lie in its simplicity. In the exclusive fund States formal hearings are practically nonexistent. New York's commission holds a hearing on every compensable accident case. The survey showed that there are a large number of different methods of computing the average weekly wages in the various States, some established in the laws, others laid down in the rules of the administrative commissions, and some the outgrowth of custom and practice in actual cases. Application of these methods has not been always consistent. Even in States with identical laws, the actual application is often very different in effect. "This suggests the desirability of standardization of methods along as simple lines as possible, covering each particular class of cases. Many States have already attempted this, some with a good degree of success, but the wide variety of methods disclosed suggests the need of simplification and uniformity in order to secure to injured workers and their dependents a prompt and full settlement of their claims."

SALINE PURGATIVES IN RELATION TO THE ABSORPTION OF OTHER DRUGS.

It appears to have been shown that when certain drugs are being given, it is unwise to prescribe subsequently or simultaneously such purgatives as prevent or retard the absorption of these drugs. It is known that magnesium sulphate, sodium sulphate, sodium phosphate, and similar salts, caused increased secretion of fluid and retardation of absorption, with the accumulation of a large amount of serous fluid in the intestines through the osmotic action of the unabsorbed salt, which, instead of being absorbed, or the basic part absorbed so gradually, draws more fluid into the intestinal lumen.

Dr. D. T. Macht and Mr. E. M. Finesilver, of the pharmacological laboratory of Johns Hopkins University have recently been making investigations and experiments in this direction which, together with the results, they have described at some length in the *Johns Hopkins Hospital Bulletin,* September last. These experiments have established, beyond peradventure, that saline purgatives can and do affect markedly the absorption and consequent secretion of certain other drugs. These results are in keeping with the pharmacodynamics of saline purgatives.

Moreover, the experiments made it evident that the absorption and excretion of drugs, even when given by injection, are influenced to some extent by saline laxatives, after they have been administered previously by the stomach tube. The investigators state that undoubtedy this phenomenon has something to do with the concentration of the blood and the distribution of fluids in the body. It has been known for some time that saline purgatives will concentrate the blood, as is indicated by the blood count, and this has been emphasized recently by the work of J. Underhill (*Journal of Pharmacology and Experimental Therapeutics*, February, 1922). The experiments of Macht and Finesilver were made with potassium cyanide, chloretone as representative of the hypnotic group of drugs, several opium derivatives, and other alkaloids, such as cocaine, strychnine, atropine and quinindine, heart drugs, antipyretics, such as sodium salicylate, salol, aspirin, antipyrin, potassium iodide and urotropin, and of the antiseptics phenol and mercury bichloride. Macht and Finesilver are of the opinion that the results of their investigations and experiments done by physiological and chemical methods have a distinctly practical bearing, showing that it is a matter of some importance as to the kind of purgatives or laxatives administered with certain drugs. For example, experiments on cats revealed the fact that when digitalis was given with saline laxatives, its absorption and consequent toxic symptoms took place more slowly by far than when the drug was administered with water. The absorption and subsequent secretion of sulphonephthalein and sodium salicylate were affected markedly by saline purgatives. Also the absorption of phenol and mercury bichloride is affected in a like manner, which findings substantiate the findings of Macht, who in 1915 showed that the most suitable solution for lavage in acute carbolic acid poisoning was a saturated solution of sodium sulphate. It was demonstrated too that the excretion of urotropin was delayed by the administration of saline purgatives. The authors studied the relation of other laxatives, such as calomel, cascara sagrada, and castor oil in this connection, but did not find that any important influence was exerted by these drugs on the absorption and excretion of other medicaments.

VOLSTEAD.

Easily the most important protest, at least in so far as the medical profession is concerned, against the Eighteenth Amendment and the Volstead Act is the organization of the Association for the Protection of Constitutional Rights, an organization of practising physicians of New York, of which Dr. Samuel W. Lambert, of 130 East Thirty-fifth Street, is president. The whole country has an immediate and direct interest in the movement for many reasons. In the first place the medical profession, as conservators of public life and health, are a people apart, bound by the obligations of their profession to do all in their power to relieve human suffering and save human life. In the second place, they are licensed by the laws of every State in the Union to practise their profession and not to be hindered, and to exercise discretion in that practice. They spend years in training—but why enumerate?

The action is made all the more impressive by reason of the fact that the organizers are among the most prominent men in the profession in this or any other country and many of them strong advocates of total abstinence for their patients and the community generally. In its essence the matter resolves itself into the question: Has any mere legislator like Mr. Volstead, multiplied by whatever number of supporters were necessary to put through the Eighteenth Amendment and the Volstead Act, the right to prevent another—any other—from doing something which the laws of every State distinctly license him to do? The question could be thrashed out from even a more fundamental basis. Has any legislation a right to take away what no legislation can give, viz., the God given right to the exercise of his free will, in so far as that exercise does not impair the same right on the part of others? And can a man, lawfully practising his profession, by reason of that fact be made a criminal, an open and flagrant violator of the law, unfit to hold intercourse with decent, law abiding citizens, to say nothing of holding communion with his own selfrespect?

The effect of this action is to raise issues, vital both as regards the law itself and the conflict between the medical profession, or a large majority of it, and the law in a form which cannot be ignored, which must be recognized by United States Court action. Heretofore, protest has been made only spasmodically and of local or personal importance. The position of the medical profession is, or appears to be, based frankly upon a refusal to recognize the constitutionality of the amendment, or as much of it as conflicts with human rights as practised by the profession in the treatment of patients. The views of their opponents, in the existing state of public opinion, is absurd and untenable, and simply amounts to putting a premium on breaking one law as the sole means of giving relief under another.

THE BRITISH JOURNAL OF SURGERY.

One often hears expressed the opinion that men of science, so long as they have truth, care nothing for beauty. In some cases this is undoubtedly true, as, for instance, in that of the college professor recently quoted by the daily papers as having said that art is all "bunk"—only technic is to be admired. There are, however, notable exceptions to this rule. Some of these may be seen in several of the scientific publications, especially of the United States and of Great Britain. Among medical journals in this country, the *Annals of Medical History*, edited by Dr. Francis Packard, of Philadelphia, and published by

Paul B. Hoeber, of New York, stands out by reason of the beauty of its typography, illustrations, paper and general makeup. In Great Britain, the *British Journal of Surgery* is a notable example of the aesthetic possibilities to be attained by scientific publications. This magazine is edited by a committee of which Sir Berkeley G. A. Moynihan is chairman, and E. W. Hey Groves, editorial secretary. It is published in Bristol, England, by John Wright & Sons, Ltd. By the use throughout of a paper with a specially prepared glazed finish, the illustrations and plates, perhaps the special feature of the journal, are remarkably clear and definite, and permit of a wealth of the finest and most delicate detail, not only in the halftone reproductions from photographs, but also in the anatomical and surgical drawings and diagrams, which is not often found in the illustrations even of scientific works. Special attention has been given to making the color prints, appearing as plates and in the text as well, accurate and realistic. Many of the reproductions from photographs of complex surgical procedures are further illustrated by accompanying line drawings showing details. The type is rather small, but clear.

◆

News Items.

A Distinguished Foreign Visitor.—Dr. Leon Bernard, professor of hygiene in the University of Paris and secretary of the National Antituberculosis Association of France, arrived in the United States recently to spend several weeks observing American health methods.

Child Welfare Organizations Unite.—The two national organizations engaged in promoting the health of the children of this country have voted to unite under the title of American Child Health Association. The two organizations as heretofore known are the American Child Hygiene Association and the Child Health Organization of America; both having been devoted primarily to promoting the health of children.

Bequest to Pennsylvania University for a Department of Clinical Surgery.—Under the terms of a bequest made by Edmund A. W. Hunter, the University of Pennsylvania will receive $200,000 for the establishment of clinical surgery. The bequest was made with the provision that the addition to the university be known as "the Agnew and Hunter Department of Clinical Surgery" in memory of Dr. D. Hayes Agnew and Dr. Charles D. Hunter, son of the donor.

Assistants in Ophthalmology.—The Italian Medical Society of New York has been notified by the department of ophthalmology of the University of Rome, that two assistantships without salary are offered to American medical graudates of Italian extraction. Living expenses will be paid. For further information application should be made to the Societa Medica Italiana, 47 West Forty-second Street.

Dr. John J. McGrath Heads Bellevue Board of Trustees.—Dr. John J. McGrath, of 109 West Seventh-fourth Street, appointed by Mayor Hylan to serve as a member of the board of trustees of Bellevue and Allied Hospitals, was elected president of the board at a meeting of the trustees held in the hospital recently. At the same time the board drew up a resolution thanking the retiring president, Dr. John W. Brannan, for his services to the hospital.

College for Rehabilitation. — At a meeting held at the New York Academy of Medicine, a company was incorporated for the establishment of an American College of Rehabilitation for training workers in the field of reconstruction of the wounded and crippled. Major Franklin W. Johnson, of Columbia University, described the rehabilitation work carried on among disabled soldiers during and after the war. The sponsors for the new company are Dr. Fred H. Albee, Mrs. Clarence Cary, Martin A. Metzner, W. J. Hoggson, R. Gradwell, and Standish Chard.

Seventh Harvey Lecture.—The seventh Harvey Society Lecture to be given at the New York Academy of Medicine, Saturday evening, February 24, 1923, will be delivered by Dr. Leon Asher, professor of physiology, University of Berne. His subject will be The Building Up of the Organism by Chemical and Nervous Coordination and Regulation. The lecture by Dr. E. V. Cowdry, of the Rockefeller Institute for Medical Research, on The Significance of the Internal Reticular Apparatus of Golgi in Cellular Physiology, has been postponed until Saturday evening, March 10th.

An Interesting Hospital Site.—The Bronx Hospital has just purchased land for the construction of a new main building. This property has an interesting history. It was sold by Indians in 1648 to Col. Robert Morris, whose heirs held it until 1848. There was then one conveyance to James Herold, from whom the John Eichler Brewing Company bought it over fifty years ago, holding it until the present sale. With this addition to their holdings, the Bronx Hospital has a total frontage on Fulton Avenue of 211 feet and an increase of its present holdings of 151 feet on 169th Street. The old buildings will be used for a maternity hospital, nurses' training school, and dormitories.

The Dr. Sofie A. Nordhoff-Jung Cancer Research Prize.—Dr. Sofie A. Nordhoff-Jung, of Washington, D. C., has founded an annual prize of five hundred dollars bearing the title of "The Sofie A. Nordhoff-Jung Cancer Research Prize." This prize is destined for the encouragement of researches in the etiology, prevention and treatment of cancer. It will be awarded by a commission, composed of members of the University of Munich, Bavaria, and will be granted for the first time in December, 1923. The commission consists of Professor Borst, Professor Doederlein and Professor Sauerbruch, with Professor von Romberg as chairman. The award will be made as a recognition of the most conspicuous work in the world literature bearing on cancer research, done at a time antecedent to the allotment of the award. Though the prize will not be awarded on a competitive basis all research workers in cancer are invited to submit literature on this subject.

NEW YORK CITY'S PASTEUR CELEBRATIONS.

Louis Pasteur, familiarly known as "the father of bacteriology," was born on December 27, 1822. The centenary of his birth as that of perhaps the greatest scientific genius of all time has recently been celebrated in most of the large cities of the world. New York organizations and institutions held a number of these commemorative exercises in honor of the great Frenchman. January 10th was designated by the Mayor as Pasteur Day, and was celebrated in the public schools and elsewhere with appropriate exercises. The College of Physicians and Surgeons of Columbia University, in cooperation with other departments of the university, held on December 18th a memorial meeting at which the chief speaker of the evening was Emmanuel de Margerie of the University of Strasburg, exchange engineering professor from France. His subject was France's Estimate of Pasteur. Doctor Calkins, professor of protozoology, spoke on The Debt of Biology to Pasteur, and Doctor Lee, research professor of physiology, on The Debt of Medicine to Pasteur. On December 27th, Pasteur's birthday, a notable gathering took place at the American Museum of Natural History. This meeting was sponsored by the New York Mineralogical Club and the American Museum of Natural History, cooperating with the United States Department of Agriculture, the Department of Health of New York City, the New York Academy of Sciences, the New York Academy of Medicine, the Pasteur Laboratories of America, the New York State Department of Health, the Rockefeller Institute for Medical Research, and several other notable organizations. Dr. George F. Kunz, president of the New York Mineralogical Club, presided and made the introductory address. He was followed by Prof. Henry Fairfield Osborn, president of the American Museum of Natural History, who paid tribute to the great number of lives saved through Pasteur's discoveries, and emphasized his significance as a symbol of the ultimate relation between nature and the development of religious conceptions and beliefs. He represented the union of spiritual, intellectual, and physical well being. His greatest mission was to "show the way to the physical redemption of man." The next speaker the Hon. Gaston Liebert, Consul General of France, also emphasized the great scientist's belief in spiritual realities not yet probed by science, and gave a brief account of his origin and early life and their influence upon his character.

Dr. Hermann M. Biggs, health commissioner of New York State, spoke of the prophylactic treatment of rabies, Pasteur's most notable contribution to preventive medicine, and one of the most significant and important discoveries in the whole history of medicine. He outlined the history of Pasteur's work in this field, through the years of careful experimentation upon animals, with repeated successes in protecting them from developing the diseases, to the final test upon a human being in the person of the boy, Joseph Meister, who had been badly bitten by a mad dog some time before he was brought to the laboratory. The treatment was applied and proved a complete success. The publication of Pasteur's method of treatment was followed by an inrush to the laboratory in Paris by people from all over the world who had been bitten by rabid dogs. Four children sent from Newark, N. J., were the first Americans to be sent for treatment. Their expenses were paid by the *New York Herald,* and they were accompanied by Dr. Frank Billings, of Chicago. At this time Doctor Biggs was sent by the Carnegie Laboratory of the Bellevue Hospital Medical College to study the Pasteur treatment in Paris. His description of the great man in his laboratory was most interesting. Soon movements were on foot to establish Pasteur institutes in other countries. One was founded in New York, under Doctor Gibier, and later, a laboratory in Philadelphia. About 1901 the New York City Department of Health made arrangements to give free treatments. Since that time about two hundred a year have been treated, and the death rate in these cases has averaged about one half of one per cent. There has always been much discussion as to the death rate from rabies previous to the introduction of the Pasteur method of treatment; it has been estimated at between fifteen and fory per cent. In the forty years that have elapsed since the publications of Pasteur's report on the treatment of rabies, little of importance has been added to our knowledge of the disease.

Dr. George D. Stewart, president of the New York Academy of Medicine, made a brief talk, commenting upon the charm and sincerity of Pasteur's personality, which made him beloved by all and won for him at the time of his death a vote from the French people as "the greatest Frenchman." Doctor Stewart also outlined his work leading to the discovery of inoculations. Dr. Pierre Lecomte de Nouy, of the Rockefeller Institute for Medical Research, outlined Pasteur's work in bacteriology as the basis of modern surgical treatment. Lord Lister followed up this work begun by Pasteur, so that today it is no longer true, in the words of Valpeau, that "the prick of a pin is the open door to death," but, what with the sterilization of instruments, equipment, and everything that comes in contact with a patient, a surgical operation is no longer a preliminary to death from blood poisoning. Dr. Hideyo Noguchi, also of the Rockefeller Institute, said that all modern bacteriology follows the conceptions laid down by Pasteur. He was also the founder of the principle of serum therapy. He had the courage and conviction to persist in applying these principles in the face of much hostile opposition from many of his contemporaries. Major Henry J. Nichols, of the U. S. Medical Corps, gave an interesting résumé of the relation of Pasteur's work to military medicine. In the late war, about one half the deaths were due to infectious diseases. In the civil war, the proportion was three times as great. Most of the military medicine of the present day is based on the principles originated by Pasteur, including asepsis, antisepsis, and vaccination. Prof. C.-E. A. Winslow, of the department of biology and bacteriology at Yale University, outlined Pasteur's work in the four fields of science benefited by his discoveries, namely, industry, surgery, public health, and serology. His success in all the fields of his endeavor was due to his remarkable mastery of scientific experimental methods. The meeting closed with a display of lantern slides illustrating Pasteur's life, shown by Dr. Frederick Lucas, president of the New York Academy of Sciences.

Another notable celebration was that by the New York Academy of Medicine on January 10th, at which the president of the academy, Doctor Stewart, presided. The first speaker of the evening was Prof. Russell Chittenden, of Yale University, who spoke of the contributions of Pasteur as a chemist, namely, his work in the polarization of light, tartaric and racemic acids, alcoholic fermentation, etc. Dr. William H. Welch, of Johns Hopkins University, spoke on the subject of Pasteur's Contributions to Biology. He said that the great Frenchman was unique in four ways: 1, He was appreciated by men of all branches of science—physicians, chemists, biologists, surgeons, sanitarians, and agriculturists; 2, he was fortunate in his biographers; 3, his work illustrates the correlation of many branches of science—crystallography, fermentation, spontaneous generation, silkworm disease, infections, rabies—and shows an orderly progression throughout; 4, his discoveries were significant as opening up new sciences and new chapters in science. He was the founder of modern bacteriology. He made the first practical applications of public health methods. Doctor Welch believes that the opposition he encountered on the part of his contemporaries did much to emphasize his originality and to fix upon him the ultimate credit due him. His theories marked a new era in bacteriology, and he laid the foundations of our knowledge of yeast, fungi, nutrition, metabolism, sterilization, and pasteurization. The great thought that he always kept foremost in his mind was the idea of specificity. He was interested in pure as well as applied science; he felt little interest, however, in purely descriptive morphology; all his efforts were based on the significance of science to life. Dr. Erwin F. Smith, of the U. S. Department of Agriculture, spoke of Pasteur's work which retrieved the silkworm industry of France from disaster, and of how he taught the peasants to use preventive measures for the future protection of their industry.

Dr. Simon Flexner, of the Rockefeller Institute, discussed the Contributions of Pasteur to the Knowledge of Immunity and Therapy. He outlined his discovery of anthrax as a bacterial disease, of carriers of chicken cholera, and of his experiments in producing immunity by inoculation, leading ultimately to the preparation of vaccines for anthrax, chicken cholera, swine measles, and rabies. He showed also the relation of his work to modern methods of asepsis and antisepsis. Dr. Biggs spoke on the Pasteur Treatment of Rabies, and the meeting was closed by an address by Dr. William W. Keen, of Jefferson Medical College, on the Influence of Pasteur on Knowledge Concerning Surgical Infection and Puerperal Fever. Doctor Keen showed how Pasteur's discoveries as to infections laid the foundation for all modern methods for treating blood poisoning, gangrene, and other infections following surgical operations and childbirth.

This meeting at the Academy of Medicine marked the close of an interesting exhibit, opening December 27th, of Pasteur memorabilia, shown in the exhibition hall of the Academy. This was arranged chronologically to illustrate the various periods of Pasteur's life and work. It included photographs and prints of places made famous by association with his life, of members of his family and of his friends, of apparatus used by him in his work, of the Pasteur institutes in various countries, and of many other interesting relics; books and pamphlets, including biographies, and copies of his own works; autograph letters; case records; a full collection of beautiful medals and medallions commemorating himself and his work; and a number of busts, including the famous bronze bust by Naoume Aronson of Paris, loaned by him and exhibited for the first time. Other exhibits arranged in honor of the centenary were several demonstrating public health measures, shown at the American Museum of Natural History, and a number of special government exhibits sent from Washington, among them, an interesting demonstration of crystallization.

Another celebration was held on January 28th at the Town Hall under the auspices of Hon. J. J. Jusserand, Ambassador of France, Gov. Alfred E. Smith, Mayor John F. Hylan, Archbishop Patrick J. Hayes, Bishop William T. Manning, Dr. Nicholas Murray Butler, and Hon. Gaston Liebert. The hall was decorated with the Stars and Stripes and the flags of the European nations. Several musical numbers and the singing of the *Marseillaise* added interest to the program. Brigadier General S. Herbert Wolfe made the introductory address, and His Excellency, the Ambassador of France, gave a sketch of the life of Pasteur, with many interesting personal anecdotes. Dr. Butler spoke next of Pasteur's great contribution to the world, the revelation of the invisible universe, and the knowledge of it through scientific methods. "Pasteur was the apostle of work. No name in modern history is to be placed higher than his, as that of one of the chief servants and benefactors of humankind, and the first revealer of the intellectual power of man." Dr. John H. Finley was the next speaker, on The Debt of Science and Industry to Pasteur. Pasteur taught the world that there is no godliness without cleanliness. The study of chemistry turned him to the world of the infinitesimal, thence to bacteriology. Doctor Finley outlined his work with microorganisms. "He was like Prometheus—he brought a fragment of monumental truth to mankind."

Dr. Stewart, president of the Academy of Medicine, was the last speaker. He outlined the various achievements of Pasteur in chemistry leading to crystallography and the beginnings of stereochemistry and x ray spectroscopy; in fermentation, and its application to disease; in settling the question of spontaneous generation; in diseases of the silkworm, and in anthrax, chicken cholera, swine fever, and rabies. Before Pasteur, men knew about as much about symptoms and prognosis as they do now, but knowledge of causes was obscured by theory, so treatment was only guess work. Pasteur's studies in fermentation led to the investigation of causes, resulting in modern aseptic and antiseptic methods in surgical and puerperal cases. Pasteur's chief characteristics, according to Doctor Stewart, were industry, will, clear thinking, and intense patriotism. He was practical in his work rather than purely experimental.

LONDON LETTER.

(*From our own correspondent.*)

London, *January 9, 1923.*

CURATIVE SUNLIGHT.

The value of light and especially sunlight in the treatment of certain diseases is now more firmly established than ever. Dr. C. W. Saleeby, who lectured on the subject before the King Alfred School Society on January 3d, said that he wished he could substitute sunlight and milk for beef and beer in the creed of Englishmen. Experiments had shown that sunlight was an incomparable antiseptic. It killed the tubercle bacillus. No antiseptic approached the advantage of sunlight in relation to tuberculosis, and it was applicable to other diseases. Victims of tuberculosis placed in the sunlight had been transformed into healthy children. Notwithstanding all the evidence in favor of this form of treatment, all over England children were allowed to lie in the dark in institutions supported by charitably disposed persons, and these children were slowly traveling to premature graves, because the curative value of sunlight was unknown to their parents or to those who had charge of them. As a child required food, air and water, so also did it require sunlight.

GROWTH OF CHARACTER.

Dr. David Forsyth lectured recently before the National League for Health, Maternity and Child Welfare on the Growth of Character. Any leading features found in the character of the adult could, he said, be recognized by psychoanalytical investigation of the first few years of life. One of the happenings which could influence a child's character was the loss of its mother. It might ultimately cease to think of her, but the emotion felt at the time would influence its character permanently in the time to come. The birth of the second child had also its effect on the first child's mind, for it soon realized that it no longer enjoyed the love of its parents exclusively; thus were jealousy and disappointment bred. If punished for its jealousy, the child resented the attempt to check that feeling, and that had an influence on the formation of its character. Analysis had conclusively demonstrated that the first wish that could be detected was the wish to become reborn. That wish could be seen acting until adult life. There were people who were always protesting against hurry and strife. It could be traced back to their early days, when their first wish was to be done with the world straightaway.

PREVALENCE OF CANCER AND APPENDICITIS.

Diet is held by some to be the predominant cause of cancer and of appendicitis to a lesser extent. In proportion to the increase of meat consumption, according to certain authorities, cancer and appendicitis have increased, and this is the view taken by Dr. G. A. Casilis de Pury in a letter published in the *Lancet,* December 30 last. However, as Dr. Harry Campbell has pointed out in a letter published in the same journal of January 6th, preagricultural men were more carnivorous by far than human beings of the present day. There is no evidence extant that preagricultural men suffered greatly from cancer or appendicitis. Among the Esquimaux who live almost wholly on flesh, cancer is said to be unknown. While Dr. Campbell is one of those who believe that unsuitable diet does predispose to both cancer and appendicitis, he does not think that meat *per se* is responsible for this predisposition. Unsound meat may have this effect but not sound meat. Simplicity and regularity of diet, in his opinion, have more to do with warding off these two diseases than the proportion of animal food in a diet. Also Dr. Campbell is somewhat sceptical as to the alleged or apparent increase of cancer and appendicitis during recent years. He asks if this assumed increase is not to some extent attributable to improved methods of diagnosis.

CANCER RESEARCH IN 1922.

The close of the year 1922 has shown a twelve months' wonderful record of progress in the treatment of cancer and in the identification of specific causes capable of producing the disease. At the London Cancer Hospital a great deal of time has been devoted to research. Experimental cancers have been produced in small rodents by the continued application of irritant substances obtained from paraffin oil, shale oils, arsenic and soot. The results have been microscopically examined, photographed and recorded and the data thus secured, together with that of other more extensive experiments still proceeding are expected to furnish valuable indications to the specialists employed in combating the terrible scourge of cancer.

AWARD OF ROYAL SOCIETY MEDALS.

The Royal Society Medals for 1923 have been awarded as follows: The Copley Medal, to Sir Ernest Rutherford for his researches in radioactivity and atomic structure; the Rumford Medal to Professor Pieter Zeeman, for his researches in optics; a Royal Medal to Mr. J. Bancroft, for his researches in physiology, and especially for his work in connection with respiration; a Royal Medal to Mr. C. I. R. Wilson, for his researches on condensation nuclei and atmospheric electricity; the Davy Medal to Professor J. E. Thorpe, for his researches in synthetic organic chemistry; the Darwin Medal to Professor R. C. Pannett, for his researches in the science of genetics; the Buchanan Medal to Sir David Bruce, for his researches and discoveries in tropical science; the Sylvester Medal to Professor I. Levi-Civita, for his researches in geometry and mechanics; the Hughes Medal to Dr. F. W. Astor, for his discovery of isotropes of a large number of the elements by the method of positive rays.

DOCTORS AND ADVERTISING.

An important discussion took place a short time ago at a meeting of the British General Medical Council with regard to doctors and advertising. Dr. R. A. Bolam moved that it be submitted to the executive committee to consider and report upon the prevalence of oblique or indirect advertising by medical practitioners in the lay press. The object of the resolution, said the mover, was to elicit in some way a pronouncement from the council on certain developments in advertising chiefly through the lay press, which might if it were allowed to continue tend to lower the traditions of the profession in the eyes of the community. Since the issue of the council's warning seventeen years ago it was only on very rare occasions that such blatant forms of advertising, such as the distribution of hand bills commending any particular practitioner, was indulged in, but there were other more subtle and oblique methods which had gradually crept in. There was, for example, the practice of inserting in certain well known papers in the Court Circular column, in which advertisements might be included, statements in personal notices of the fact that a deceased person, for instance, was a relative of "so and so," the well known physician. Then there was the case of notices of engagements of marriage, in which the opportunity was seized for retailing for public consumption the qualifications and the address of the bridegroom or the father of either of the contracting parties.

Objection might also be taken to the notice of the fact that a certain person had returned from illness, and was now resuming his occupation at a certain address, and giving the telephone number. Notices such as these might come very readily within the definition of an advertisement. In the ordinary lay press practitioners were advertising either unwittingly or with their consent. Correspondence often appeared over the names of medical men expressing opinions on various subjects. Then there were advertisements of practitioners by or in connection with the condition of their patients.

There were cases of more or less direct advertising. One was where the doctor advertised that he received patients at a certain address, and that certain advantages were to be obtained at that address for a specified fee. The name of the doctor was not given, but the system of a box number reference was adopted. Dr. Bolam went on to refer to various cases which had occurred during the past few months of interviews in the lay press with general practitioners. They ranged from a chronicle of the experiences of doctors of liners at sea, who performed operations by wireless and combatted epidemics, and there were portraits and the specific names of those gentlemen in interviews on such important subjects as the spread of cancer and the possibilities of its treatment, wherein the gentlemen concerned were described as experts on this particular subject, and their names were given, together with sufficient information as to where they were to be found. Moreover, Dr. Bolam observed that women doctors were not immune from the indiscretions of journalism. There existed, however, he proceeded to say, a much more serious state of affairs where deliberate intent might be imputed to the practitioners involved. There was the case of the reputed communication by one person to a series of lay papers on one specific topic, in which occurred some such phrase as "my extended experience" in a certain type of work. It was important that the public should be informed on all matters of importance involving medical questions, and if the object of this publicity was the proper instruction of the public, then it was quite right that the articles should appear, but he did not think that the names of the medical writers should be given. Generally speaking, the medical men who were most often quoted in the press were not necessarily those whose opinions carried most weight in the medical profession or with the educated public. The extension of such a system as now prevailed might lead to a competition for public notice, in which the abler and more scrupulous members of the profession must be left behind the men who were professionally inferior, which would thus destroy the traditions of selfrespect which had given the profession its present high status. On the suggestion of Sir Donald McAlister, president of the General Medical Council, Dr. Bolam altered his resolution to read, that it be remitted to the executive committee, in consultation with the legal adviser, to consider and report upon the expediency of amending the council's warning notice with effect to canvassing and advertising, so as to make its scope more clear and comprehensive.

It may be said that while direct advertising by medical practitioners can be easily and effectively dealt with by the General Medical Council, the prevention of indirect advertising is very difficult. The definition of advertising, or rather as to what constitutes an advertisement, is in itself difficult. Distinction between the ethical and unethical notice of a medical practitioner in the lay press is hard to draw. Still the warning from the General Medical Council should serve its purpose.

SMALLPOX AND VACCINATION.

The outbreak of smallpox of virulent type in London, which has not wholly subsided, is no doubt largely due to the unprotected state of the population. Smallpox in its worst form was practically stamped out before the war. Within recent years many thousands of people have evaded the Vaccination Act, 1907, on the plea of conscientious objection to the procedure. A large proportion of these had no valid objection to vaccination, but evaded their obligation with regard to their offspring in order to save themselves a few days' inconvenience. There is a large section of the population of this country unprotected against the disease, and there are also on all sides an ample stock of smallpox virus ready for importation. Consequently, with these two factors in operation, it might be difficult to prevent the development of an epidemic, even with the greatest watchfulness.

In answer to a question asked in the House of Commons on November 29th last, Major Boyd-Carpenter said the present outbreak of smallpox was not confined to London. Cases of the disease had occurred during the present year in fifty-six districts outside London and in seven metropolitan boroughs; 893 cases had been discovered and twenty-six deaths had occurred; in 275 of the cases the patients had been vaccinated; 608 were either unvaccinated or showed no evidence of vaccination; and in seven cases there was no information as to vaccination.

GLAND THERAPY.

Gland therapy is very much to the front in these days and considerable progress is continually being made in this direction. The importance of the internal secretions is becoming more and more obvious and consequently means to keep these in smooth working order are being sought. The first triumph of organotherapy was with medicinal preparations of the thyroid and it seems that the latest is the discovery of insulin, or rather the obtaining of insulin, which it is stated has the most favorable effect upon diabetes. While it is early yet to predict that a cure has been found for diabetes, at least it can be said that the omens are propitious and augur well for future successes in the field of gland therapy.

Book Reviews

THE WORKS OF PASTEUR.

Oeuvres de Pasteur. Tome Premier Dissémtrie Moléculaire Tome II. Fermentations et Générations Dites Spontanées. Paris: Masson et Cie Paris, 1922.

The works of Pasteur have been assembled and are being brought out under the able editorship of Pasteur Vallery-Radot. This will be a distinct boon to medical literature. The papers of Pasteur have been scattered through many diverse channels, journals of chemistry, reports, private correspondence, and have found lodging in many sundry places. These two volumes are the first of seven which will be brought out in chronological form. The first contains his work on crystals, molecular dysymmetry. The second is devoted to fermentation and socalled spontaneous generation. These works, coming at the time when the great master's centenary is being observed, should receive a wide reading. They are interesting, not only from the tremendous rôle they played in firmly establishing present scientific medicine, but they give an insight into the mind and methods of one of the world's most painstaking workers. When we consider the quality of work he did as revealed from his original work and the improvements that have since developed in laboratory facilities, we more than ever wonder how he was able to achieve his tremendous results. The world was enriched by this great man. We can learn a great deal from his works. We owe a debt of gratitude to Pasteur Vallery-Radot for the compilation of this important work.

DEMENTIA PRECOX.

The Constitutional Factors in Dementia Precox. By Nolan W. C. Lewis. Illustrated. New York and Washington: Nervous and Mental Disease Publishing Company, 1923.

Much work has been done by various observers on the constitutional factors in dementia precox. This monograph by Lewis is one of the most fundamental that has appeared. His approach has been the most logical and his survey the most extensive. Most important among his pathological findings is the small size of the heart. The universality of this cardiac deficiency, which by the way does not admit of hypertrophic changes under stress, has been noted in the dementia precox cases of the hebephrenic and catatonic types alone. The paranoid types present a distinct pathology the nature of which he promises to discuss in a future communication. Another point worthy of consideration is the susceptibility of the patients to tuberculosis. This, it may be argued, could be due to the institutional life led by the patients, but the absence of a similar occurrence in other forms of mental disorder and the possible relationship between the cardiac deficiency, organic and functional as well as the inability of organic compensation, would lead to the acceptance of Lewis's hypothesis.

Important among the findings is the general atrophic or sclerotic condition of practically all the glands of internal secretion. This includes thyroid, adrenals, pituitary, and gonads. This would correlate the findings of Mott and Such of England and Madrid and certain Swiss and German workers. The difficulty in the past has been the attempt to fix the blame on some one set of these glands. From the autopsy reports in this monograph it will be seen that the lesions are widespread and have some common etiological source.

This monograph is the first in the series where illustrations have been used. No doubt this innovation will find favor for other works of psychiatry and will enhance their value.

On the whole this work of Lewis's should be read with care by all interested in the widespread disease of dementia precox. To have a work of this character done here in America will reflect to the credit of the man and the institution where he was able to bring his researches to a conclusion. In the last few years by far the most valuable work done in psychiatry in this country has come from St. Elizabeth Hospital in Washington. Standing in the foreground is the work of Kempf and now this excellent monograph by Lewis. This has been made possible through the influence of Dr. William A. White, who has done his share in bringing psychiatry into its own in this country. But this should be a review of Lewis's book and too much praise could not be given it. However, it is certain that he would not object to a word of commendation to that excellent institution in which he formulated his conclusions. This book of his should have a wide reading.

FREUD.

Vorlesingen zur einführung in die Psychoanalyse. Von Prof. Dr. Sigm. Freud. Vierte, durchgesehene auflage. Mein Internationaler Psychoanalytischer Verlag, 1922.

The fourth edition of the original German text of Freud's well known lectures which appeared in this country under the title of *A General Introduction to Psychoanalysis.* The book contains a series of thirty-eight lectures. In its pages we meet Freud the genial genius as he presents the groundwork of his findings in that vast and hidden world, the unconscious. He begins with the simple lessons learned in the processes of forgetting and goes on to the use of psychoanalytic therapy. For those who are familiar with German no happier medium could be selected for a study of the fundamental factors involved in Freud's theories.

REPRODUCTION.

The Physiology of Reproduction. By Francis H. A. Marshall, with contributions by William Cramer, James Lochhead and Cresswell Shearer. Second revised edition. New York and London: Longmans Green & Co., 1922.

We are fortunate in having a book of this type written, or more properly supervised, by so able and conscientious a worker as Marshall. Of the importance of this topic there can be no doubt. Moreover, too little consideration has been given this most important subject in general works on physiology. To find a reason for this would not be difficult, for the taboo on sex has extended to science as well as the world we live in.

Marshall has presented his topic from many angles and created a monumental book—a book that may well serve as a source book to those engaged in many fields. The physician will find many points of interest and practical value. The recent findings in endocrinology as related to the gonads have been included. Some of Steinach's experimental work is carefully reproduced. Gynecologists, anthropologists, students of sexology and many others will find much useful information here. This second edition has long been needed, for the first was out of print and nothing has replaced it.

EAR, NOSE, AND THROAT.

Diseases of the Ear, Nose and Throat. Medical and Surgical. By WENDELL CHRISTOPHER PHILLIPS, M.D. Sixth Revised Edition. Philadelphia: F. A. Davis Co., 1922.

The latest edition of this standard work contains a number of notable additions which materially increase its value as a textbook of reference for the practitioner and of instruction for the student. The chapters on the adult tonsil, on chronic ethmoiditis, on suspension laryngoscopy, on bronchoscopy and esophagoscopy, on blood tests in the septic intracranial complications of otitis media, and others have been revised, and that on laryngectomy for malignant disease of the larynx has been greatly extended and elaborated. Some methods and procedures which have become obsolete have been eliminated, such as a number of the old punch operations on the nasal septum. The illustrations are numerous and, generally, of a high degree of excellence technically and educationally. The best, perhaps, are the semidiagrammatic drawings by Bosse from life. The photographs of operative scenes are, on the other hand, somewhat lacking in definition of detail. Phillips's work is of necessity a bit sketchy in its consideration of physiology and pathology of audition, equilibration, and respiration, but there are no significant omissions. The author is to be congratulated on the way he has brought his work up to the level of the times and, in particular, on the chapters dealing with tests for rotational nystagmus, the operations for purulent labyrinthitis, and that on sinus thrombosis.

OBSTETRICS.

Obstetrics for Nurses. By EVERETT DUDLEY PLASS, M.D. New York and London: D. Appleton & Co., 1922.

The author has endeavored to furnish the nurse with a condensed textbook on obstetrics, which is intended to be an improvement on existing books couched in such language as she can understand and stripped of all unnecessary details. The detailed instructions in technic have been omitted intentionally, as hospitals vary their technic according to their individual needs. It is not a practical treatise, but rather a scientific work, upon which the nurse may base her practical nursing. However, the scientific and theoretical aspects of obstetrics are treated in a manner far in advance of the nurse's needs; in fact the book could serve as an excellent primer of obstetrics for medical students. While it is true that the nurse is the hand maiden of the physician and should therefore know and be conversant in medical matters, especially in the matter of educating the public in such matters (an important part of her duties), most of the material contained in this book can never be used for that purpose; besides, the subjects that would be of popular interest are not sufficiently emphasized. The author admits that his book is a condensation of Williams's *Obstetrics* and as such it can, at best, serve the nurse only as a reference book. For that it is most suitable.

PERICARDITIS.

Bibliotheque des Connaissances Medicales. Dirgee parle DR. APERT. Les Pericardites Aigues, par DR. BLECHMANN. 27 Figures. Paris: Flammarion, 1922. Pp. 278.

This small volume is devoted to a presentation of the etiology, symptomatology and treatment of acute pericarditis. The difficulty of diagnosis is reviewed and the many signs and symptoms which have from time to time been considered pathognomonic of this condition are critically discussed. The author makes frequent references to the work of other men but, unfortunately, gives no bibliography. The latter would contribute a good deal to the value of the book. For the exploratory puncture of the pericardium, Dr. Blechmann recommends the epigastric route, inserting the needle in the median line at the tip of the xiphoid cartilage. Several chapters are devoted to a critical review of the indications for and the various methods of pericardiotomy. The monograph can be recommended as presenting an adequate review of the subject.

EXERCISE.

Physical Exercises for Invalids and Convalescents. By EDWARD H. OCHSNER. Second Edition. St. Louis: C. V. Mosby Company, 1922.

This booklet is designed as a manual of calisthenics for convalescent patients and for sedentary workers who do little physical work. It should be of real value to physicians in planning exercises for their patients. The exercises are well described and illustrated.

DIABETES.

A Clinical Treatise on Diabetes Mellitus. By MARCEL LABBÉ, M.D. Translated, revised and edited by Charles Greene Cumston, M.D. With Four New Chapters by the Author and Three by the Editor not included in the French Edition. New York: William Wood & Co., 1922. Pp. viii-382.

This book is the result of the author's many years of experience in the symptomatology and treatment of diabetes; it also includes a discussion of the pathogenesis and pathology of this disease. Great stress is laid upon the metabolic study of the diabetic patient —much more than is found in most treatises on the subject. The significance of various symptoms are studied in the light of these metabolic investigations. The relation of diabetes to epilepsy, typhoid fever, edemas and tuberculosis is taken up in detail. The treatment of tuberculosis in diabetes, of intertrigo and of erythema of the vulva is given. The possibility of an infectious origin of diabetes is discussed. The hepatic, pancreatic and bronzed forms of diabetes and their underlying pathology are dilated upon. Diabetes is also studied in its relation to endocrinology and metabolism. The various forms of treatment are evaluated. The clinical aspects of acidosis and diabetic coma and their treatment are given special attention. The biochemistry of diabetes is not neglected.

On the whole, this book strikes one as being something different from the usual run of treatises on this subject. Much of what has been said in the past is here viewed from an entirely different angle. Some of the theories expressed are novel and unique; many of the author's conclusions are quite illuminating and seem to be distinct advances in the study of this subject, in view of the fact that there is still much to be learned about this somewhat obscure disease, constantly increasing in frequency.

NEUROPSYCHIATRY.

System der Neurose. Von Dr. Emil Kügler, Berlin, Wein: Urban und Schwarzenberg, 1922.

A rather presumptuous title for the material presented. Kügler leans toward a mechanistic foundation for the basis of his work. There is much interesting material presented although it cannot all be classed as fundamental.

ULCER.

Neuere Auschanungen vom Wesen des Ulcus pepticum ventriculi und Duodeni. Von B. Gruber und E. Katzenstein. Halle a.S: Carl Marhold Verlagsbuchhandlung, 1922.

Gruber and Katzenstein coincide with Hart's views that the prognosis of duodenal ulcer is about the same as that of gastric ulcer. With regard to the transformation of a peptic ulcer into cancer the authors are inclined to consider such an event quite rare. The statistics of Hansemann and Ronjetzny show that about three to five per cent. of gastric cancers take their origin from an ulcer.

DERMATOLOGY.

Lehrbuch der Hautkrankheiten fur Aerzte und Studierende. Von Prof. Dr. Max Joseph. Neunte Auflage. Leipzig: Georg Thieme, 1922.

The present edition of this well known publication has been abbreviated to a considerable extent at the request of the publishers for commercial reasons. The author's desire to amplify his eighth edition in all directions would have placed the cost of the work beyond the limits of the consumers' purse. Nevertheless all of the recent advances have been incorporated.

SOCIAL WORK.

A Form of Record for Hospital Social Work. By Gertrude L. Farmer. Philadelphia, London, and Montreal: J. B. Lippincott Co., 1921.

The six chapters of the little manual of eighty-one pages are devoted to choice of record form; the short service record, the five by eight record, the extension folder, further uses of the extension record system and illustrative records. While primarily intended for hospital extension work and for the benefit of the discharged patient the matter is naturally of interest to all social workers.

PROHIBITION.

The Eighteenth Amendment. By Charles Taber Stout. New York: Mitchell Kennerly, 1921. Pp. x-216.

An important topic is badly handled in this book on prohibition. While the American Medical Association may have many faults—this we shall not discuss for the moment—yet it is unfair to accuse them of iniquities of which they are guiltless. An unmerited attack is made upon one of the workers of the College of Physicians and Surgeons of Columbia University, which proves nothing. There is enough evil to combat without unjust accusation. Better and more fundamental data should have been used to make the book of value.

PARASITES.

Die durch tierische Parasiten hervorgernfenen chirurgischen Erkrankungen der Bauchhohle. Von Prof. Dr. H. Kehl. Halle a.S: Verlag von Marhold, 1922.

Kehl recommends an anus preternaturalis cæcalis in severe cases of chronic amebic dysentery. Kehl does not wait too long before advocating this procedure. Whenever there is sufficient suspicion of a liver abscess Kehl advocates exploratory puncture and, if pus is found, immediate operation. In echinococcus of the liver, operation is always indicated, as there is as yet no other way of treating this affection. The monograph is very instructive and deserves commendation.

GOUT.

La Goutte et Sa Cure Cure Hydro-minerale (Etudes d'Hydrologie Clinique). Par le Professeur agrége Maurice Loeper, et les Docteurs Flurin, Glenard, Joly, Paillord, Piatot et Pierra. Price 7 francs. Paris: L'Expansion Scientifique, 1921.

This brochure of 144 pages comprises seven essays. Loeper begins with uric and oxalic acid gout, Piatot discusses the articular, muscular, and remalgiform symptoms of gout, Joly gouty phlebitis, Flurin gouty bronchitis, Pierra uterine congestion of the gouty, while Paillard and Glenard cover the hydromineral treatment of gout.

PSYCHIATRY.

Untersuchungen Uber Die Korporlichen Störgen bei Geisteskranken, Von Otto Wuth, mit 63 textabbildungen. Berlin: Von Julius Springer, **1922.**

A carefully compiled statistical study of laboratory findings in the various psychoses and epilepsies. Much original work of value is presented with a most extensively compiled literature.

TUBERCULOSIS.

A History of the National Tuberculosis Association. By S. Adolphus Knopf. New York: National Tuberculosis Association, 1922.

The progress of this institution, founded in 1904, is reported in salient detail. The early struggles of the association in its pioneer stages, in the combat with tuberculosis, and the final organization of the National Tuberculosis Association, are described. A large number of bibliographical sketches and photographs of the men engaged in this most humane and constructive work are presented. The book, however, would be more complete and accurate if our very modest author would tell of some of his own energetic activities in the movement. Those who know how tireless he has been and how earnestly he has applied himself will regret the fact that he did not make adequate mention of his work. The book should prove of great value in many fields. Dr. Knopf is to be congratulated on the service he has rendered.

FICTION.

Escape. By Jeffery E. Jeffery. New York: Thomas Seltzer, 1922. Pp. 325.

Emmy, the heroine of the book, is, after her father's death, the one thinking member of a hopelessly stupid, hidebound, middleclass English family. She finds their limited, smug suburban life unbearable, and starts on a career of "escape." The possession of good looks, a good mind, and practical ability carry her along through "Emancipation," in which, after a dull period of married life from which Providence kindly relieves her, she enters upon a remunerative professional venture, attended eventually with the luxury of a London flat and educated, well to do friends. In the next part of the story, "Illusions," she finds her comparatively luxurious life far from satisfying, her work unfruitful of all but material compensations, and a love episode, based upon passion alone, barren of everything but disillusionment. She finally solves her problem of escape in "Compromise," by discovering that there is no escape, as she conceived it, for those big enough to live life fully and truly. Freedom lies only in the capacity to adjust to the rules of life's contest; in subordinating the individual to a purpose that serves the whole. Personal growth comes from contacts that mean, not security and satisfaction of self alone, but an effort to adjust and to grasp new and larger meanings. The basis of this new progress comes to be for Emmy in her married life with Barty, a free thinker of socialistic tendencies, who has the visionary's scorn of his wife's common sense and practical appreciation of the value of money, but whose ideals of a larger life lead Emmy out of her narrow, individualistic lines of thought and action. Alike in their realization that service alone gives meaning to living, and in their love for each other, they yet differ sufficiently to stimulate always a mutual interest, and to ensure a mutual development. The book is well written and the story admirably told. Throughout the reader has a rare sense of actuality, naturalness and wholesomeness.

SOUTH SEAS.

Atolls of the Sun. By FREDERICK O'BRIEN. New York: Century Co., 1922. Pp. 508.

Another, the third of O'Brien's charming, intimate descriptions of his South Sea experiences. Adventure, unusual situations and quaint episodes, all with the background of Polynesian beauty, make the book replete with interest. This is O'Brien's third visit and his third book. He is a conscientious writer and his readers are rewarded by his painstaking sincerity.

◆

Medicoliterary Notes.

The Harvard University Press has issued a series of eleven small volumes under the general title *Harvard Health Talks.* Each booklet consists of a lecture delivered at the Harvard Medical School by a prominent physician. Among the subjects covered are diseases of the tonsils, the skin and the heart, cancer, and pneumonia.

* * *

The autobiography of Madame Curie will be published in the near future by the Macmillan Company.

* * *

In view of the frequent difficulty in securing a sufficient number of competent physicians in outpatient departments of hospitals, the Associated Out-Patient Clinics of the City of New York have released a circular showing how the establishment of a proper relationship between the ward service and the outpatient service will tend to solve the above mentioned difficulty and to add to the efficiency of both services. Four principles are recommended and explained: 1, Unified organization of hospital and outpatient staffs; 2, continuous service, signifying that the director or responsible head of each service be continuously in charge, and that the principle of continuity of care of the patient be maintained; 3, a unified system of medical histories for both departments, with a single record room for both; 4, the use of outpatient departments for education and research by practising physicians and by institutions affiliated with medical schools or with postgraduate work.

* * *

Penal Discipline is the title of one of Dutton's recent publications. Its author is Mary Gordon, an Englishwoman who was for many years an inspector of prisons. The book studies and compares the penal systems of the United States, France and Holland.

* * *

In a digest of its forthcoming annual report the clinic of the Cornell University Medical College states that distinct progress has been made during this first year of its effort to provide medical service to persons of moderate means, without interfering with the practice of the private physician. The Clinic holds five afternoon and two evening sessions every week. During the year 113,981 visits were made to these sessions by 22,409 persons.

* * *

McClure's Magazine is running a series of popular articles on child psychology. The January number contains the first of these. The Backward Child and the Prodigy, by Ruth Danenhower Wilson, who takes the stand that the backward child has been shown to possess as great an opportunity for success as does the infant prodigy. Among examples of stupid children, she quotes the names of Sir Walter Scott, Darwin, Linnaeus, Poe, Whistler, and Rousseau.

* * *

Representative Cable of Ohio offered a resolution in the House on December 30th requiring the application of the intelligence tests used by the army to immigrants in order to perfect the present tests.

* * *

Harper's Magazine for January contains several articles of unusual interest, among them a rather satirical discussion by Katharine Fullerton Gerould of American socalled freedom, entitled Freedom in the Land of the Free; Gamaliel Bradford has a study of Benedict Arnold; W. L. George contributes one of his inimitable essays called The Art of Courtship; Sheila Kaye-Smith has a short story on A Day in a Woman's Life.

* * *

Walter de la Mare has in the *Yale Review* for January a charming fantasy called Lispett, Lispett & Vaine, the story of a house who have for many years been the creators of marvellously beautiful fabrics. De la Mare is this year's recipient of the famous James Tait Black Memorial Prize offered by Edinburgh University for the best novel of the year, in their opinion, *Memoirs of a Midget.* Last year D. H. Lawrence was awarded the prize for *The Lost Girl.*

Practical Therapeutics

THE USE OF TRANSFUSION IN CONDITIONS OTHER THAN ANEMIA.

By Edward H. Goodman, M. D.,
and John Speese, M. D.,
Philadelphia.

In presenting this brief paper we are not armed with a large series of cases, but fortified merely with the conviction, that the time is set for an extension of medical indications for the use of transfusion. Transfusion of blood from man to man or from animals to man dates back almost as far as the art of healing itself, but not until recent times has the procedure been made so safe that its employment may be regarded as almost free of danger. The discovery of three distinct groups of isoagglutinins by Landsteiner and the discovery by Moss and almost synchronously by Ottenberg of four groups placed the risk of causing damage by promiscuous blood transfusions upon those who transfuse in disregard of proper grouping and removed any risk from those who perform transfusion, observing previously the laws of proper typing. The technic of the operation, if such a title does not carry too much import, has been perfected so that any one may easily learn its details, and the giving of a transfusion, by the citrate method, amounts to scarcely more than the giving of normal salt solution by vein. There is at the present time a debate concerning the advantages of whole blood, and the disadvantage of citrated blood, and vice versa, a question which scarcely concerns us, although in passing we confess to the use of the citrate method.

There can be no doubt about certain conditions which are distinctly benefited by transfusion, notably anemia from hemorrhage and anemia from blood disease. The literature of the past five years concerning these teems with records which leave no room for cavil. Here and there in this mass of literature one finds reference to other uses for transfusion, to indications for its employment in cases other than anemia. We find shouts of approval from those who have made use of it in sepsis following war injuries, an echo to this of its possible value in other forms of sepsis, loud praises of its virtue in eclampsia, a whisper of its success in nephritis, a plea for its trial in acidosis. In French articles we find an adventurous spirit transfusing convalescent typhoid blood to check the course of active typhoid fever, transfusing variola patient with convalescent smallpox blood, using transfusion in meningococcemia, measles, scarlet fever, influenza, bacillary dysentery, diphtheria, tuberculosis, intoxications, pregnancy, pellagra, benzol and gas poisoning. Not always do we find success, for failure awaited the observer in dysentery, tuberculosis, and in diphtheria, but nevertheless, these researches in biochemistry and immunology proceed.

Our experience parallels in no wise that of the man with many case records, except in one particular, our interest in extending the indications for transfusion. We have seen benefit follow its use in cases of infection (organism determined or undetermined) in cases of blood dyscrasia (purpura, persistent bleeding of unknown origin) in bronchopneumonia and in cases of eclampsia and in nephritis, and it is because of these benefits that this paper is presented.

As far as sepsis cases are concerned, it has been suggested that blood be used which has been made antibacterial by the injection of vaccines made from the patient's infectious process, the idea being the same as that prompting physicians to use convalescent influenza-pneumonia serum in influenzal pneumonia. We have not made use of this suggestion but have employed normal typed blood. The effect of the blood in sepsis is to lessen the anemia, to supply active leucocytes, to raise blood pressure and by all three to add to the natural defenses of the patient. The real value is from stimulation of the tissues to increased cell proliferation, and according to Polak, this is obtained not from the quantity but rather from early and repeated small infusions which enable the patient to immunize himself. The use of 250 to 300 c. c. every third day is recommended.

In blood dyscrasias with evidences of deficient clot forming constituents in the blood, large amounts seem advisable. The frequency of injection depends upon the clinical course of the disease, but one large transfusion may suffice.

In nephritis we have used it a few times; in acute cases with some temporary benefit, and in chronic cases with secondary anemia, with marked improvement in the blood picture and resulting benefit to the patient.

In bronchopneumonia we have employed transfusion with the greatest benefit and shall in the future recognize its potentiality and call upon it for assistance in these cases for which otherwise we have done so little.

We have seen no harm follow transfusion and in the experience of one of us (S) reactions after citrated blood have been infrequent and of slight degree. The grouping has been done with the extremest care by Dr. Eiman, of the Presbyterian Hospital, and no Group IV has been used unless the donor and recipient both belong to this group, and then cross agglutination is practised. It has been suggested that the low percentage of reactions may in a measure be ascribed to this.

An advantage of the citrate method in purely medical cases such as nephritis, bronchopneumonia, and certain types of sepsis is that the donor's blood can be collected out of the patient's sight, can be carried to his bedside, and there given with no more shock to the sensibilities than that accompanying an ordinary vein puncture.

Sulphemoglobinemia.—V. R. Mason and F. D. Conroy (*Bulletin of the Johns Hopkins Hospital*, December, 1921) report a case of sulphemoglobinemia, which is the thirteenth proved instance of this condition on record. After describing the patient's history, they discuss the clinical features of this condition, the diagnosis, pathogenesis, and treatment.

Read before the American Therapeutic Society, May 2, 1922.

Alcohol Injection in Facial Neuralgia.—Wilfred Harris (*Lancet,* July 15, 1922) states that concentrated alcohol coagulates the albuminous elements of the nerve fibres and dissolves the fatty sheath of Schwann. Degeneration downward of the nerve then results from the point of injection (neurolysis). The regeneration of the nerve fibres takes place as usual and may be more or less complete in two years. In the author's experience, the sensation never returns so fully in the third division of the nerve as it does after injection of the second division. If the nerve is properly injected, the freedom from neuralgia may be practically guaranteed for twelve months, and in the majority of the author's cases it lasted much longer, ranging up to thirteen years in one case of involvement of the third division; the usual period is four to five years. In many scores of cases in which the author injected the Gasserian ganglion with a resulting total anesthesia, the author sees no reason why the cure may not be as permanent as with complete gasserectomy or resection of the sensory root behind the ganglion, although the injection treatment is infinitely less severe a procedure and is practically free from risk when done by an expert. Nevertheless, it is not an operation to be attempted until considerable experience has been gained with this treatment.

Modern Treatment of Tabes and Paresis.—E. Mattauschek (*Wiener klinische Wochenschrift,* August 3, 1922) states that in every fresh case of tabes, regardless of the stage of the disease, the specific therapy should be a combined mercury arsphenamine course of treatment; if crises or severe pains appear during the course of treatment the mercury can be omitted temporarily and the dose of the arsphenamine can be reduced. During or after the second half of the treatment, iodine should be given in daily doses of two to five gm. If the treatment is successful, it should be repeated within a year; in stationary rudimentary cases, and in those with single objective symptoms, the repetition of the course may be delayed longer. With insufficient and transient improvement, the treatment should be repeated after six months, combined possibly with the nonspecific remedies, such as tuberculin, typhoid vaccine, the treatment for malaria or recurrent fever and sodium nucleinate. In torpid cases with insufficient and inadequate reactions of the spinal fluid, such a combined treatment should be tried in the very beginning. In severe acute ataxia, only arsphenamine and iodine are indicated. For very advanced cases, arsphenamine alone, or combined with roborants and symptomatic treatment, is indicated.

The general treatment consists of measures to maintain and increase the patient's strength, the avoidance of cold water treatments and the use of thermal baths and the baths and water drinking at Hall, Gastein, and Teplitz. For pains, antineuralgic remedies, especially pyramidon, moist packs, hot air, saline baths, d'Arsonvalization, high frequency and diathermy and in obstinate cases, radium emanation are indicated. In the most intense, obstinate and obstreperous cases, surgical procedures are indicated. If the pains are localized in definite root areas, the injection of 0.5 per cent. novocaine adrenaline solution into the sites of exit of the nerve roots may be tried. The surgical treatment also includes the intradural or extradural division of the particular posterior roots affected. Gastric crises may require a few drops of cocaine or amyl nitrite, repeated doses of six to ten drops of adrenaline, codeine, belladonna suppositories, morphine and atropine, or lumbar puncture. Morphine sometimes aggravates the condition.

If all of these measures should fail, such surgical measures as stretching of the solar plexus, resection of the splanchnic nerve, gangliectomy, division of the vagus branches at the cardia with subsequent gastroenterostomy, or division of the painful fibres of the anterolateral tracts of the spinal cord at the level of the uppermost dorsal segments, are indicated, but these are all measures of the last resort. To prevent infection of the bladder, it should be emptied at regular intervals. If the bladder is overdistended, manual expression of the urine may be tried before resorting to catheterization. In severe disturbances of bladder function (hypertonic bladder with the formation of trabeculæ) the intravesical division of the sphincter or an excision of a wedge from the posterior commissure of the internal urethral orifice of the urethra has been recommended. The ataxia is treated by reeducation; it is contraindicated, however, in far advanced cachectic cases with severe cardiac and vascular affections and in those with severe joint changes. This treatment should be given methodically and (at least in the beginning) by the physician himself. The hypotonic muscular conditions require orthopedic treatment.

Dibromin, an Improved Surgical Disinfectant.—Francois de Martigny (*Canadian Practitioner,* May, 1922) states that some very interesting and impressive observations were recently made at Hôpital Francais in a study of forty-five septic surgical cases treated with solutions of dibromin. This preparation is a bromine compound. It is a pure, chemical, crystalline substance, colorless and odorless, containing fifty per cent. bromine (debrom-malonyl-ureide). It is rapidly soluble in water and will remain stable in solution for at least a week. The chemical stability of dibromin is an important factor, as it will remain in its original form indefinitely, if put into gelatin capsules and kept dry. In this form the preparation can be conveniently used for making exemporaneous solutions when desired. This feature alone seems to have solved the problem that has always confronted the surgeon who formerly used chlorine compounds. Unpublished reports of laboratory tests show that dibromin is a very active germicide as compared to phenol, acriflavine, and iodine. This is especially true when tested against such pathogenic organisms as Bacillus pyocyaneus, Streptococcus hemolyticus, Staphylococcus aureus, Bacillus diphtheria and pneumococcus. This bromine compound appears to have a selective action on bacteria by reason of the oxidizing effect of the bromine, and at the same time shows little or no effect upon animal tissue. It is also devoid of objectionable properties such as toxicity, odor, instability, and taste. The majority of chemical substances which have been employed as germicides or antiseptics, while effective, unfortunately possess other properties which limit their use on living tissue. Dibromin is comparatively nonirritating when fresh solutions of proper strength are used.

Proceedings of Societies

SOUTHERN MEDICAL ASSOCIATION.

Sixteenth Annual Meeting, Held at Chattanooga, Tenn., November 13 to 16, 1922.

The President, Dr. Seale Harris, of Birmingham, Ala., in the Chair.

(Continued from page 187)

Glucose Tolerance Test in Malignancy of Digestive Tract.—Dr. Sidney K. Simon and Dr. J. Holmes Smith, Jr., of New Orleans, stated that the glucose tolerance test was carried out in forty-five cases. In fifteen the diagnosis of carcinoma was definitely proved; nine, or sixty per cent., of the patients gave a typical high sustained curve. In one case a high but atypical sustained curve was present, yielding a total of sixty-six and two thirds per cent., giving a sustained typical or atypical curve among the cancer patients. One case of pulmonary tuberculosis likewise furnished a type I sustained curve. A new type involving a relatively low percentage of blood sugar at the forty-five minute reading was observed, which was sustained to the end of the two hour period. They did not believe that this type was of significance in the diagnosis of malignancy. While not specific for carcinoma, a certain type of glucose tolerance curve was observed in a majority of patients suffering from carcinoma of the digestive organs. After excluding diabetes mellitus, tuberculosis and hyperthyroidism, the type I or type II curve in conjunction with characteristic clinical evidence would lend strong support to the diagnosis of malignancy.

Diagnosis and Treatment of Tetany.—Dr. Stewart R. Roberts, of Atlanta, Ga., stated that the treatment of tetany called for certain therapeutic indications, which once understood permitted the details to fashion themselves easily. The convulsions and spasms should be stopped, laryngospasm relieved, and the irritability of the nervous system lessened. During the acute attack cow's milk should be withdrawn or greatly diminished and cereals and gruels substituted. In older children and adults the fresh vegetables containing vitamines were in order. A well balanced diet was indicated when possible. Hygienic measures were particularly important. In one case the child improved materially when given abundant fresh air and sunshine. When tetany was associated with another disease which bore a casual relation to it, treatment of the primary disease was essential.

Acute Otitis Media in Children.—Dr. Joseph B. Greene, of Asheville, N. C., emphasized the following points: The difference in the anatomy of the temporal bone and adjacent structures of infants and children from that of adults. Our duty in urging all measures possible for the prevention of middle ear diseases and the importance of instituting prompt and appropriate treatment as soon as symptoms arise. The importance of early incision of the drum membrane without waiting for all the cardinal symptoms and the marked changes in the tympanic membrance, keeping in mind the fact that it was safer to operate a day too early than an hour too late.

Direct Intubation in Neglected and Desperate Cases of Tracheal and Bronchial Diphtheria.—Dr. Clyde E. Purcell, of Paducah, Ky., stated that with direct intubation and bronchoscopy we could practically eliminate tracheotomy in the management of diphtheritic stenoses. Tracheotomized patients required very skilled nursing. However, intubation cases with ordinary nursing were not such a problem. It must not be understood that this was a panacea for diphtheric stenotic complications. If a patient had no lung complication, no kidney involvement, and was not profoundly septic from absorption of toxins, the two means we had at hand, together with massive doses of antitoxin, ought to save a great majority of these patients. So far, he said he had been able to save every one.

Eye Lesions of Nasal Origin.—Dr. Joseph D. Heitger, of Louisville, Ky., said that in all eye lesions, regardless of possible etiology, one must be ever mindful of the nasal sinuses as a possible etiology. Repeated careful examinations with proper illumination were often necessary to disclose small easily overlooked changes in the postethmosphenoidal district which might be productive of ocular lesions. Sluder's careful clinical description, coupled with Wright's histopathological diagnoses based on Sluder's specimens removed at operation offered the most practical approach to the study of eye lesions of nasal origin. Early differential diagnosis and complete operation when treatment failed to produce rapid results were of great importance in the prognosis of ocular lesions of nasal origin. More qualified use of the word pressure was needed in the literature dealing with eye lesions of nasal origin. Closer intensive group study was necessary if progress was to continue.

Clinical Observations Following the Use of Cyanide of Mercury in Lenticular Opacities.—Dr. John H. Burleson, of San Antonio, Texas, said that all cases injected the patients showed improvement; those with metabolic disturbance relapsed. All cases traceable to infection had apparently been benefited. Twenty cases showing opacities of the crystalline lens had been studied to determine the relation of the blood sugar to etiology. Seventeen of the twenty cases showed an increased blood sugar percentage. The lowest blood sugar was 1.24 gm. to the litre; the highest was 3.00 gm. to the litre. Graded glucose tolerance tests in three of these cases showed blood sugar curves similar to those found in early diabetes.

The Problem of Obscure Nose and Throat Affections.—Dr. Edward A. Looper, of Baltimore, Md., said it was important to recognize focal infections in the upper respiratory tract at the earliest possible time, before toxic absorption had produced permanent degenerative changes. As many of these cases were difficult to determine because of indefinite local pathology, we must be governed in our final opinion by a careful study of the general symptoms and the reaction in remote structures. For this reason a careful history was necessary. Complete physical examinations were important. Investigation of eye symptoms and changes in other organs might lead to the development of factors which proved to be the deciding element in a final analysis of the case.

Surgical Treatment of Diseases of the Gallbladder.—Dr. Irvin Abell, of Louisville, Ky., stated that eighteen of the 411 cholecystectomies in his series had previous cholecystostomies. Some of these had been done for cholecystitis without stones; most of them for cholecystitis with stones. In three of the patients primarily operated on by him the stone formation existing at the second operation greatly exceeded that found at the first operation. Of sixty-six patients operated on for common duct stone, seven had a previous cholecystectomy. The great variation in the pathological anatomy afforded by the size, number and distribution of the stones, and the degree and extent of the inflammatory edema and infiltration contributed greatly to the difficulty of making a complete removal. In 394 cases the stones were found in the gallbladder in 339, the common duct in thirty-one, the hepatic duct in one, and the entire tract in twenty-three.

Gallbladder Disease.—Dr. Martin E. Rehfuss, of Philadelphia, Pa., stated that one ought always to be on guard for possible associated disease of which most common were chronic appendicitis, chronic colitis, and chronic lesions of the stomach and duodenum. It was his rule to urge operation when medical treatment failed to produce amelioration of symptoms and failed to produce a cessation of the acute attack. He urged operation when there were gross deformities in the upper right quadrant, usually demonstrable by the x ray, and in the presence of acute inflammatory diseases under precisely the same condition that one would operate in acute appendicitis. In the presence of common duct block, or in the presence of chronic gallbladder disease at the malignancy age, when the patient failed to register any improvement, after an appreciable period of medical treatment, the physician was warranted in attempting surgery.

Socalled Perthe's Disease.—Dr. F. Walter Carruthers, of Little Rock, Ark., stated that the clinical picture presented was of a child usually between the ages of six and eight or older, with a history of a fall four or six months previous, now limping, and complaining of one leg tiring easily. There was a slight deformity at the hip and the child was unable to bring the leg inward without some pain and especially on marked abduction the pain was severe. Flexion and extension were apparently normal, and there was possibly a little shortening of the limb. Bryant's triangle showed and the condition was unilateral. Treatment should consist in relief of weight bearing, whether by rest in bed or by some mechanical appliance, regardless of the fact that this condition was considered a self-limiting disease of two or three years.

Clinical Aspects of Botulism.—Dr. J. C. Geiger, of Chicago, Ill., stated that there was considerable variation as to the susceptibility of guineapigs to botulinus intoxication with spores. There was a considerable difference of results in animals inoculated subcutaneously and fed with spores. Unquestionably spores might remain latent in tissues of animals for many weeks without the animal showing any indication of the disease. It was comparatively easy to isolate the spores of Bacillus botulinus from practically every tissue of the body after feeding or subcutaneous inoculation of the spores. There might be a quantitative relationship both of the feeding and subcutaneous inoculation as to the number of spores. Epidemiological and experimental evidence seemed conclusive that Type A was predominant in outbreaks among human beings in America, and was probably the more toxic.

Arthroplasty.—Dr. Frank D. Dickson, of Kansas City, Mo., said that cases of arthroplasty should be carefully selected. An adequate incision should be used so that a good exposure might be secured. Sufficient bone should be removed to allow free motion. In the aftertreatment, the use of traction with early movement gave the most satisfactory results. The earlier the voluntary control of the joint was established, the better the range of motion.

Tendon Transplantation.—Dr. Wyatt S. Roberts, of Birmingham, Ala., said that tendon transplantation was a brilliant contribution to the surgery of paralytic deformities. Much of the experimentation of the earlier years had given way to conservatism. Procedures of known worth should, as a rule, be employed and perfected by more careful selection of cases, by improvement of the operative technic, and more thoroughly supervised aftertreatment. These points should be remembered and practised in each case.

Fractures of the Neck of the Femur.—Dr. Duncan Eve, of Nashville, Tenn., said that operative treatment of fractures of the femoral neck was not very popular and should only be undertaken in young and middleaged persons, in whom retention in correct position seemed impossible. If an open operation was decided upon a fluoroscopic examination should be made to determine that extension and abduction had succeeded in bringing the fragments in apposition. A small incision should then be made through the skin over the external aspect of the great trochanter, and usually an eight or ten penny nail driven through the trochanter and neck into the head for fixation. A plaster of Paris cast was then applied with a trapdoor cut out over the site of the incision. An ivory peg, instead of a nail might be used, in which case the trochanter and neck were drilled before the peg was placed. In ununited fractures of the neck of the femur, autogenous bone grafts promised the best results, if the patient was physically able to undergo the operative procedure and subsequent confinement. The operation should never be performed on a very old person.

Intestinal Obstruction.—Dr. T. W. Holmes, of Winona, Miss., stated that since the mortality was in direct ratio to the time of onset to the time of operation, early operation was to be urged. Each late case was a problem unto itself and called for keen surgical judgment. The anesthetic should be nitrous oxide oxygen, or local anesthesia might be employed. The toxemia should be combatted and neutralized by fluids in abundance, hypodermoclysis, gastric lavage, etc. Carbohydrates should be administered and proteins avoided.

(*To be concluded.*)

Abstracts from Current Literature

GASTROENTEROLOGY.

New Culture Medium for Intestinal Flora.—D. Chalmers Watson (*Lancet,* July 15, 1922) proposes a saccharose milk agar medium. The broth (using bullock's heart) is made as follows: Meat extract, 1000 c. c.; peptone 10 gm.; sodium chloride 5 gm. This mixture is evaporated down to one fifth original bulk and then made up to the original bulk with whole milk; two per cent. saccharose is added after the medium has been neutralized with tenth normal sodium hydroxide solution. With the use of this medium it was found that in contrast to all the other media commonly used for primary culture, the growth of gram positive organisms, mainly of the streptococcal forms, increases from an average of five per cent. or less up to an average of forty-five or fifty per cent. With this medium a film is obtained which compares favorably with the original smear and while favoring the growth of streptococci it does not inhibit the growth of coliform organisms. The vaccines are usually prepared from the organisms which grow on the media in common use, and the author believes that the cause of the profound derangement of the normal flora is to be found in the relation to the bacteria which do not readily grow on the ordinary media, but are revealed by the use of this new medium. The possible significance of variations in the hydrogen ion concentration of the media should not be overlooked. Further investigations along these lines is necessary.

A Case of Hyperplastic Variety of Intestinal Tuberculosis.—S. R. Klein (*Western Medical Times,* July, 1922) refers to a rare form of intestinal tuberculosis associated with a markedly thickened intestinal wall the result of the formation of tubercles in the mucosa and muscularis. The mucosa may show only atrophy and little or no caseation. It usually affects the ileocecal region and involves any intestinal coils adherent to the primary lesion. There may be strictures of the intestines at intervals with normal or less advanced stages of the disease in the intervening portions. Near the constrictions the peritoneum is usually studded with pedunculated masses of tubercles and the neighboring mesentery is thickened and infiltrated with tuberculous granulation tissue. The corresponding mesenteric glands are tuberculous. Polypoid tuberculous masses may project into the lumen of the bowel; these may be covered with normal or atrophic mucosa, but they rarely ulcerate. In some cases there are no typical tubercles but the tissues are infiltrated with round cells without epithelioid cells or caseation, although many tubercle bacilli can be found between the cells of the infiltration. This condition is usually primary and rarely associated with pulmonary disease; its slow development and its peculiar pathology point to an infection with a strain of tubercle bacillus of low virulence. The symptoms are often vague. Diarrhea and constipation may alternate or either one may be predominant. Colicky pains, transient and slight or severe and persistent, may occur in the lower part of the abdomen, accompanied by nausea and vomiting. Thirst may be marked. Tubercle bacilli are found in the stools and in the more advanced cases chronic diarrhea is usually present. The prognosis is very good. A case is reported in which the patient could retain nothing in his stomach and vomited immediately after taking food. He was treated with boiled milk and lime water. He is still alive after six years, constantly gaining in weight and improving his general condition.

Effect of Saline Purgatives on the Absorption of Other Drugs.—D. I. Macht and E. M. Finesilver (*Bulletin of the Johns Hopkins Hospital,* September, 1922) describe experiments which show that saline purgatives markedly affect the absorption and consequent excretion of other drugs. All the drugs used in this study were markedly delayed in their absorption from the stomach and intestines when they were administered subsequently to or even simultaneously with saline laxatives. The drugs studied were phenolsulphonephthalein, chloretone, apomorphine, morphine, pantopon, cocaine, strychnine, atropine, digitalis, convallaria, sodium salicylate, salol, aspirin, antipyrine, lactophenin, potassium iodide, hexamethylenamin, phenol and bichloride of mercury. The absorption and subsequent secretion of phenolsulphonephthalein and sodium salicylate were markedly affected by saline purgatives, even when the former drugs were given by intramuscular or intraperitoneal injection. No important effect on the absorption of the drugs from the stomach and intestines was exerted by laxatives other than those of the saline type. The results reported have an important practical bearing on the therapeutic administration of medicaments. The experiments, particularly those with phenol and mercuric chloride, speak in favor of a more extensive employment of saline laxatives in toxicological cases.

The Use of the Van den Bergh Test in the Differentiation of the Obstructive from Other Types of Jaundice.—J. W. McNee (*British Medical Journal,* May 6, 1922) found that the chief clinical value of this test is that with it jaundice due to obstruction of the main bile ducts by carcinoma, hepatic cirrhosis, obstruction in the portal fissure or gallstone in the common bile duct can be clearly differentiated from jaundice of hemolytic origin or from functional derangement of the liver cells, as hemolytic and alcoholic jaundice and functional jaundice, such as catarrhal jaundice, toxic jaundice of infective diseases (typhoid fever and pneumonia), and icterus neonatorum.

It consists of Ehrlich's diazo reaction applied to the blood serum: To one c. c. of the serum in a small test tube 0.25 c. c. of freshly prepared diazo reagent is added. One of three events may follow: 1. An immediate reaction in ten to thirty seconds, showing a bluish violet color, the intensity depending upon the amount of bilirubin present. 2. A delayed reaction after one to fifteen minutes or longer, showing a reddish color which gradually deepens and becomes more violet. This has been replaced by the indirect reaction. 3. A biphasic reaction after ten to thirty seconds, showing a slight reddish color, which after one minute or longer gradually deepens and becomes more violet. The immediate or direct reaction denotes obstructive jaundice. If this is not obtained, add two c. c. of a ninety-six per cent. alcohol to one c. c. serum, the mixture is centrifuged to precipitate the albumin. To one c. c. of the supernatant fluid add 0.5 c. c. alcohol and 0.25 c. c. diazo reagent: if bilirubin is present in the fluid a maximal violet red color obtains at once. Where a perfect indirect reaction results, the jaundice is either hemolytic or due to some functional liver cell derangement without obstruction.

The mechanism of this test depends upon the fact that where bilirubin gives only the indirect test, the pigment is bound to the albuminoid substances in the serum and the union is only broken by time or alcoholic precipitation. The bilirubin differs molecularly in the two conditions. The biphasic reaction depends upon the presence of both types of bilirubin in different proportions in the same serum. The biphasic test should, at present, not be used to draw absolute conclusions. The author found it present in uncompensated chronic valvular disease, the icterus at first being functional in nature and later of the obstructive type, corresponding to the degree of hepatic engorgement. In cases of suspected carcinoma of the liver or the exit of a calculus from the common bile duct, it is important to estimate the increase or decrease of the bile pigment in the serum, especially in obstructive jaundice and in the latent jaundice of pernicious anemia. The indirect test can also be used for colorimetric quantitative determinations of bilirubin.

Etiological Relationship of Gallstones to Cancer of the Gallbladder.—In an extensive study, Ludwig v. Aldor (*Wiener klinische Wochenschrift,* May 25, 1922) arrives at the following conclusions: 1. The opinion usually held that gallstones are in etiological relationship to cancer is untenable because it is based on the onesided, frequent coincidence of cancer and calculus. 2. This belief does not take cognizance of the fact that very often calculi are not associated with cancer. 3. The easily demonstrable disparity in the frequency of cancer and calculus speaks against an etiological relationship. 4. The systematic pathological investigations of Aschoff and Backmeister do not justify the assumption of a relationship. 5. Symptoms referable to cholelithiasis are usually not obtainable in the histories of cases of cancer of the gallbladder. Yearly observations of 360 cases of cholelithiasis over long periods of time showed that although the cholelithiasis existed in sixty-four per cent. of the cases for one to ten years and in thirty-six per cent. of the cases for ten to forty years, nevertheless the clinical picture did not warrant the assumption in a single case that the calculous process underwent transition into a cancerous one. 6. If there were positive proof for the assumption of an etiological relationship between calculus and cancer of the gallbladder, not only would there be a greater justification for an early operation, but it would also have to be remembered that in every laparotomy the gallbladder should also be examined and any calculi removed. As this etiological relationship is not demonstrable, it is not justifiable to frighten patients suffering from gallstone with the possibility of cancer in the future.

OBSTETRICS.

Pernicious Vomiting of Pregnancy.—Carlton Oldfield (*British Medical Journal,* May 20, 1922) believes that all cases of pernicious vomiting are neurotic in origin and treats them accordingly. In a series of twenty-nine cases all the patients recovered and abortion was induced in only one case. The patient is admitted to a hospital and put on an ordinary diet at once. The attending nurse is told to consider the case one of neurosis, that a bowl must not be provided even if vomiting occurs, and that the words vomit and sickness must not be mentioned in the sickroom. The patient must be expected to take her food just like other patients and must not be persuaded to do so. Usually the patient will take the ordinary diet at once, part of which may be vomited occasionally, when the patient should be assured that the vomiting will soon stop. A rectal infusion of four per cent. glucose solution is usually given continuously by the drop method for the purpose of relieving thirst and exhaustion and also to diminish the acidosis. No drugs except purgatives (when necessary) are given. These patients do better in a ward than in a private room and under the direct observation of the obstetrical surgeon. The author considers toxemia the result, not the cause, of vomiting.

Treatment of Severe Vomiting of Pregnancy.—J. A. Gabastou (*Semana Medica de Buenos Aires*), after advising several other measures, often found of service for the relief of this condition, refers to the necessity of reducing the blood pressure, which is always high. This tension, he says, is to be charged to the glands of internal secretion. It is easy to see how the corpus luteum may be the inciting cause by a gradual weakening, as pregnancy progresses, of its defensive power against the autotoxemia of that condition. The suprarenal glands, whose normal and pathological action in pregnancy is well established, may, by a recognized effect of insufficiency or hypoadrenalism consequent upon the increased task imposed by the gravid state, take part in bringing on vomiting of a severity proportional to their development. Administration of these extracts then is among the measures to be taken in overcoming the toxin whose presence is the occasion of the vomiting.

A Case of Vagitus Uterinus.—Th. Johannsen (*Zentralblatt für Gynäkologie,* June 24, 1922) believes that vagitus uterinus occurs in patients who are delivered instrumentally. He reports a case in which a forceps had to be applied because the head would not enter the pelvis; the cervix was rigid. During the forceps delivery the author, bystanders, and the patient heard a distinct cry of the child. The cord was found wound twice around the child's neck and it therefore must have been very tense and constricted as a result of the forceps delivery. It is difficult to determine how much the infantile cry was due to external stimulation (the application of forceps), but if that were the case vagitus uterinus ought to occur more frequently. The child could not have breathed deeply, as the delivery took place some time after the cry and the child, in spite of the double encircling of the neck by the cord, was not asphyxiated and cried lustily after delivery.

SURGERY.

Radical Cure of Inguinal Hernia.—R. V. Slattery (*Irish Journal of Medical Science,* November, 1922) presents the following operation, which he believes to be superior to others. The Trendelenburg position facilitates the operation, and, where possible, should be adopted. 1. The external oblique aponeurosis is exposed as in Bassini's operation. Before dividing it the anterior aspect of Poupart's ligament is exposed. 2. The external oblique is incised from the external ring to slightly beyond the internal ring. 3. The sac is freed from the surrounding fasciæ and cord starting at the internal abdominal ring. If small, the sac is ligated and removed; if large, or very adherent, the sac is ligated at the internal ring, and divided; the lower end is left. 4. The cord is freed from its bed, and retracted upwards, exposing the fascial floor of the inguinal canal. 5. The fascial floor of the inguinal canal is incised midway between Poupart's ligament and the structures of the conjoined tendon, care being taken not to damage the deep epigastric vessels. This incision is carried into the enlarged internal abdominal ring. It is essential to divide thoroughly the fascia transversalis. This is accomplished when the retroperitoneal fatty tissue is reached, which, when the patient is in the Trendelenburg position, will fall away from the fascia transversalis bringing with it the deep epigastric vessels. 6. The fascia transversalis is freed gently from the retroperitoneal fatty tissue, both upwards under the conjoined tendon, and downwards to expose the deep aspect of Poupart's ligament. 7. The fleshy arch of the internal oblique muscle is retracted upwards, and tissue forceps are applied to the divided fascia transversalis beneath it. This fascia is drawn into the wound, and it brings with it the lower aponeurotic portion of the transversalis muscle. The lower flap of the transversalis fascia is drawn forwards with Poupart's ligament. 8. Mattress sutures—four generally suffice—are used to approximate the fused fascia and aponeurosis to the deep aspect of Poupart's ligament, the innermost suture being introduced first. The aim of this suture is to unite the lower tendinous border of the transversalis muscle with its attached transversalis fascia to Poupart's ligament. The next suture also unites to Poupart the fused tendinous lower border of the transversalis muscle and fascia. The two outer sutures unite strong fascia transversalis to Poupart's ligament. These sutures should be passed deep to the lower flap of the transversalis fascia, as it is important that this should not intervene between Poupart's ligament and the structures to be united to it. By carefully drawing Poupart's ligament forward, and passing the needle from within outward to emerge where Poupart's ligament blends with the fascia lata of the thigh, these sutures are easily and safely introduced. When tying the mattress suture nearest the internal abdominal ring, care must be taken not to narrow that ring unduly. When these sutures are tied it will be seen that the internal oblique, as well as the transversalis muscle, are closely approximated to Poupart's ligament, and that there is a sound floor to the inguinal canal. 9. The cord is allowed to fall back into its bed. 10. The external oblique aponeurosis is stitched up, and the wound closed. The main advantages of this operation are: 1. The normal anatomical structure of the inguinal canal is not altered; the distance between the internal abdominal ring and the external is not diminished. The internal abdominal ring lies under the supporting muscular fibres of the internal oblique. 2. There is freedom from pressure on the cord with thorough repair of the internal abdominal ring, as the structures of the cord in that region are of very small bulk. 3. Convalescence is rapid. 4. The operation is applicable to all oblique and direct hernias.

Late Treatment of Fractures of the Long Bones of the Lower Extremity.—John T. O'Ferrall (*New Orleans Medical and Surgical Journal,* October, 1922) makes the following points: Fractures when properly reduced have sufficient union soon thereafter to permit function of adjacent joints. This joint function should be begun within a period of three weeks and is imperative. Continuous splinting without observation and joint function is condemned. Callus in the repair of bones begins to form at once but is not sufficiently hard to permit weight bearing without protection for a period of from four to six months. The function of joints adjacent to fractures is better accomplished by active motion carefully done than by passive motion. Protection of fractures of the lower extremity, at the same time permitting walking, is best done by means of the caliper splint which transfers the weight to the pelvis. The proper measurements for a caliper splint are extremely simple and should be familiar to all engaged in fracture work.

Chronic Arthritis.—L. T. Swain (*Journal of Bone and Joint Surgery,* July, 1922) concludes that there are three distinct types of arthritis: infectious, atrophic, and hypertrophic. These types differ etiologically, pathologically, and clinically, and in x rays. They respond to treatment differently and should, therefore, be differentiated. Clinical data seem valueless unless these types are studied as separate pathological entities.

Clinical Errors in the Diagnosis of Acute Contagious Diseases*

By HARRY R. LITCHFIELD, M.D.,
and LEON H. DEMBO M.D.,
New York.

How encouraging it must be to the vast army of research workers to think of the day when all contagious diseases will be controlled. Little did Von Behring, a quarter of a century ago, realize that he had laid the foundation for the control of another of the contagious diseases by the introduction of active human immunization against diphtheria by means of toxin antitoxin. Even that most dreaded contagion, scarlet fever, in its severest form, is beginning to show a lessened mortality wherever convalescent human blood serum, originally introduced by Weissbecker in 1896, is used. Where our tireless workers in that fascinating field of research have failed to provide serums, vaccines, or other means to combat disease, clinicians and public health experts, with their modern methods for disease prevention, are gradually making conditions so uncomfortable for the activities of the microbe as a pathogenic agent, that, were correct diagnoses more frequently made, their labors would be sufficiently rewarded.

From the large number of cases coming under observation at this hospital, we have been able to note many atypical syndromes and peculiarities in the character and distribution of rashes, which are responsible, to a great degree, for many errors in diagnosis by those unacquainted with the clinical pranks often played by these diseases.

There is usually considerable difficulty attending the diagnosis of the exanthemata in their prodromal stages. The general demand upon the physician for an exact diagnosis of every case before its complete evolution, is founded on an erroneous conception, and the sooner this is recognized, the better for all concerned. Few cases, when seen early, are so urgent that we cannot wait a few hours at least either to verify or to remove our suspicions. In the best interest of the patient it is wise to withhold an absolute opinion until sufficient evidence appears to warrant a reasonably certain diagnosis. Again, in view of the necessary observance of quarantine regulations, we must not jump too quickly at conclusions, but must consider carefully the facts relative to the character of the onset and the clinical picture before us.

In presenting the case reports with points illustrative of the atypical clinical features forming the basis for frequent diagnostic errors, we shall supplement discussions of the differential diagnosis of the individual diseases with descriptions of the more common typical cases.

MEASLES.

Concerning measles, with all our recently acquired knowledge of diagnostic methods, signs, spots and clinical pictures, it should not be difficult to establish a diagnosis in frank cases, but where variations in the usual clinical syndromes are encountered, our difficulties begin. To the usual clinical description of this disease we can add little; but before going into the variety of common mistakes met with in diagnostic work, a few points for comparison may be discussed here to advantage.

The onset, in the vast number of cases seen at this institution, is with what we term the triple C complex: coryza, conjunctivitis and cough. The coryza is usually moderate, the conjunctivitis simple and the cough slight. The buccal mucous membrane is inflamed and studded with small, raised, pin point, pearly white spots. These spots—Koplik's spots—may also be found on the mucous membrane in the region of the lower lip, and occasionally may be seen on the congested caruncle at the inner canthus of the eye. These appear from two to three days before the morbilliform eruption. The combination of symptoms and signs just described constitute the essential basis for a diagnosis. In association with these may be mentioned photophobia, sore throat, fever ranging from 102 to 104 degrees, headache and not infrequently diarrhea. The rash usually appears within three to four days of the onset of the disease. It is characterized at first by small macules, of a pale red color, irregular in shape, and appearing first behind the ears, at the hair line, on the forehead,

cheeks and temples. These rapidly spread to the neck, chest, trunk and extremities, soon assuming a papular character and rapidly coalescing to form the socalled crescentic eruption. The rash, at its height, is of a dark red, blotchy appearance, and within twenty-four hours the evolution is complete. The fever usually reaches its maximum at the height of the rash. Coincident with the full development of the eruption, the respiratory symptoms are intensified. The eyes secrete freely, the cough becomes worse, diffuse coarse and fine râles can be heard in the chest, the superficial lymphatic glands are enlarged, and there is great restlessness and irritability. In the uncomplicated cases the rash begins to fade on the second or third day of the eruptive period, with a simultaneous decline of the temperature and an abatement of all symptoms. On the seventh or eighth day there is a fine, branny desquamation. This last is by no means constant.

We shall forego a discussion of the differential diagnosis, since our case reports, besides illustrating some common mistakes in the interpretation of symptoms, will emphasize certain differential points. The following case, while fortunately not an example of a common error, nevertheless illustrates well the wide range of error made possible by careless examinations and partial ignorance of the usual symptoms and signs associated with this disease.

Case I.—A four year old boy was admitted to a children's hospital, having been sent in by a physician who had made a diagnosis of typhoid fever. The child had a moderate nasal discharge, edema of the conjunctivæ, especially of the lower lids, a slight cough, and a moderately congested throat. The temperature was elevated to 102 degrees and a casual examination of the buccal mucous membrane revealed typical Koplik's spots. The skin was negative regarding eruptions. A diagnosis of measles was immediately made, and the child placed in isolation. The doctor who had referred the case was insistent that the prevailing condition was typhoid fever, arguing that the spots on the mucous membrane were those of an herpetic stomatitis. The following day Widal test and blood culture were reported negative, and within twenty-four hours a typical maculopapular eruption appeared, reaching its maximum twelve hours later. The diagnosis of measles was then conceded.

The fever and respiratory symptoms presented might have led one to be suspicious of the prodromes of a typhoid invasion. The presence of the spots on a greatly inflamed mucous membrane, in association with the coryza, conjunctivitis and cough, should at once have disclosed the nature of the disease. As to the possibility of these spots being an herpetic stomatitis, a more careful observation would have ruled this out as a factor in the diagnosis. The lesions in this type of stomatitis are characterized by small, yellowish, discrete areas surrounded by zones of hyperemia. Occasionally they become confluent, giving the appearance of placques. These appear in successive crops, the favorite site being the inner surface of the lips, although they may occur in any part of the oral cavity. The resemblance to Koplik's spots, if any, is slight, and a careful survey makes a differentiation easy.

Conversely, it is not uncommon to meet with cases which have been diagnosed as measles because of the presence of what appear to be Koplik's spots. These pseudo Koplik spots occur commonly in a condition known as Fordyce's disease, recently described by Regan (1) as a not infrequent cause of mistakes in the diagnosis of measles. This is described as a chronic disease of the mouth and lips characterized by the presence of whitish or yellowish, scanty or abundant, discrete bodies, often coalescent, occurring most frequently on the inside of the mouth, laterally along the line of teeth as far back as the last molar, and less frequently on the inner surface of the lips. The lesions are pinpoint to pinhead in size and of an oatmeal color. They are almost invariably imperceptible to touch, situated on a level with the buccal mucosa, and occasionally have hairy projections. The disease is common between the ages of twenty and forty years, but has been observed in young children. The exact etiology is not definitely known apparently. Fordyce considered it the result of a granular change in the protoplasm of the cells of the affected mucosa. Regan further states that well marked cases of this disease are unusual in very young children, but that slightly marked cases are frequently seen even in infancy. The following case illustrates an error in the differentiation of this condition from rubeola:

Case II.—An infant of eighteen months was seen in the admitting room, having been sent in with a diagnosis of measles. Examination revealed a greatly undernourished child with an extensive dermatitis involving portions of the scalp and face. The oral mucosa, the lips, and the buccal mucous membrane were studded with these pseudo Koplik spots. There was no fever, respiratory symptoms were lacking, and there was no morbilliform eruption. These small, yellowish white areas did not conform in any way to the characteristic Koplik's spots seen in measles. A diagnosis of Fordyce's disease was made and the case referred to the pediatric department of an adjacent hospital.

Mistakes in diagnosis frequently arise as a result of a hurried examination of an existing rash without regard to its character and distribution. It would seem, from cases which we have observed, that there is a tendency on the part of many to regard almost any rash of a suggestive nature as indicative of the acute exanthemata. While it is true that the eruption is a strong feature in these cases, yet there are so many other factors involved as causes for similar types of rashes, that the history and clinical symptoms and signs warrant a more careful consideration before random conclusions are drawn.

An important clinical variation from the usual type of onset of measles often leads to errors in diagnosis. We refer to acute spasmodic laryngitis as an early symptom, the occurrence of which has many times brought cases of measles to the diphtheria pavilion with a diagnosis of laryngeal diphtheria. The laryngeal stridor in most instances is so marked as to make one strongly suspicious that a true diphtheritic croup is the underlying condition, and in the absence of a rash this view is further strengthened. A close inspection of the buccal mucous membrane, however, invariably reveals Koplik's spots. We are speaking now of the early stage, not of a croup as a complication in the later stages.

In the absence of characteristic Koplik's spots, by far the best method for absolute verification is a direct laryngoscopic examination, to note the presence or absence of membrane. The following case further emphasizes this point:

CASE III.—J. L., a white female child of three and a half years had had fever all day, but played about until bedtime. Shortly after midnight she awoke and coughed several times. The mother described this cough as dry and hard, and stated further that about an hour later the child breathed with difficulty. A physician saw her about three hours later and made a diagnosis of laryngeal diphtheria. Upon admission she was moderately cyanosed and a fairly well marked inspiratory dyspnea was noted. Retractions were moderate, she was very restless, and it appeared that she might very soon require intubation. However, after watching her for a few minutes, the respirations seemed to be less difficult, her color improved, and she seemed more comfortable. Physical examination at this time revealed a simple conjunctivitis, moderate nasal discharge, and an inflamed buccal mucosa. There were no Koplik's spots visible at this time. The throat was congested but there was no exudate. The cervical glands were moderately enlarged. There was no skin eruption. Laryngoscopic examination showed a moderate congestion of the aryepiglottic folds and the vocal cords, but no membrane in the larynx. Measles was suspected and the child was accordingly placed in isolation. Subsequent examination on the following day brought to light typical Koplik's spots, and two days later a well developed rash.

There are several clinical features which characterize laryngeal diphtheria. The onset is usually slow, and the stridor increases progressively without intermission. The respiratory difficulty is both inspiratory and expiratory. In acute spasmodic laryngitis the onset is sudden, usually preceded by moderate cough and hoarseness. The child awakens suddenly, as in the case just cited, with a barking, metallic cough, and a noisy stenotic inspiration. The face is cyanotic, there is marked inspiratory retraction, and moderate prostration. The dyspnea, however, is not progressive, but instead there are intervals during which the severity of the spasm diminishes. The entire attack is short in duration, and constitutional symptoms are very slight.

DIPHTHERIA.

Mistakes in the diagnosis of this disease are perhaps more frequently made than in any of the other contagious diseases. There are, of course, many factors which enter into the sphere of diagnostic error. The throat manifestations are often atypical. There may be just a very small portion of membrane in an early case which is easily overlooked in a hurried and careless examination, or, in many instances, because of poor light at the time of inspection of the throat. Again, many cases at the onset are characterized by small follicular patches on the tonsils, having an appearance similar to follicular tonsillitis. Later these coalesce to form a typical membrane, but delay in the administration of antitoxin in this disease is costly; hence the great importance of early diagnosis. Fortunately, the profession has been educated to the early administration of antitoxin in doubtful cases without waiting for culture reports. Regarding cultures we feel safe in stating that their value lies only as a means of verification. To await reports on throat cultures before instituting the proper tratement is nothing short of folly. The clinical features are far more important, and even when one feels that the picture is incomplete, antitoxin should be injected.

The streptococcic exudate seen in the throat in cases of scarlet fever is not infrequently mistaken for diphtheria exudate, and, unless a careful examination is made for evidences of an existing rash and the associated symptoms and signs, a diagnosis of diphtheria is made. The case here appended illustrates this.

CASE IV.—A colored boy was admitted to the diphtheria pavilion, a diagnosis of pharyngeal diphtheria having been made by an outside physician. The throat revealed a follicular tonsillar exudate, and a moderate amount on the posterior pharyngeal wall. It was of a mucoid character, and the pharynx, pillars, uvula and tonsils were markedly congested and edematous. The inflammatory reaction appeared greater than that usually seen in pharyngeal diphtheria. The boy appeared very ill, the temperature was 103 degrees, and the skin appeared to have an abnormal flush. (This can be seen frequently in colored patients). A careful examination brought to light the characteristic erythematous flush of scarlet fever, rapidly assuming a punctiform appearance. This case was immediately transferred to the scarlet fever pavilion.

In a differential diagnosis under the circumstances just cited, it should be borne in mind that the congested throat in scarlatina is fairly characteristic, being of a dark red color and revealing, upon close inspection, the characteristic enanthem. The inflammation is proportionately much greater than that seen in diphtheria. The exudate is mucoid in character, usually, of a greyish color, and does not assume the features of a membrane. The tongue is also an important diagnostic feature, being of a beefy appearance, with the papillæ raised and prominent, the posterior portion usually coated. The marked rise in temperature and the characteristic rash serve to differentiate further. A history of sudden onset with headache, sore throat and vomiting, in addition to the symptoms and signs enumerated, leaves little doubt as to the prevailing condition. There are, of course, many causes for the production of a scarlatiniform rash other than scarlet fever, which we shall discuss presently.

A not uncommon source of error lies in the syphilitic throat, the associated mucous patches often being mistaken for a diphtheria membrane. The following case is of particular interest in this respect.

CASE V.—J. L., forty years old, white male, was sent in from one of the city hospitals, a diagnosis of diphtheria having been made following an examination of the throat. He had been ill five days, and had been under treatment for lues. The hospital records showed that he had a four plus Wassermann (blood). He had been sent to hospital for an acute exacerbation of a chronic nephritis. Examination in our admitting room revealed characteristic mucous patches at the base of the tongue, both sides of the palate, and extending over the anterior pillars. There was marked peritonsillar edema. The liver was palpable four fingers' breadth below the costal margin. Throat cultures were all negative. Six thousand units of antitoxin were injected intramuscularly, and, although he was under observation for twelve days, there was no change in the throat condition, the patches remaining. He was accordingly transferred to another hospital for specific treatment.

NASAL DIPHTHERIA.

We have confined ourselves, thus far, to a discussion of pharyngeal diphtheria. In nasal diphtheria, while the possibility for diagnostic errors is not as great, one condition must be mentioned which is commonly confused with this form of diphtheria. Congenital syphilis, with the characteristic snuffles, nasal discharge and skin lesions could, in the majority of instances, be correctly diagnosed if the proper amount of time were devoted to eliciting a careful history and to a careful examination. It is the case in which hurried observations are made that finds its way into the diphtheria pavilion. The following case is illustrative:

Case VI.—A male, white child of thirteen months was brought to the admitting room as a case of nasal diphtheria. He had previously been ill for two weeks at another hospital, having been treated for malnutrition. The child was greatly undernourished, had a diffuse skin eruption and a well marked nasal discharge, of a seropurulent character. There was a well marked iritis of both eyes, and there was a characteristic saddle nose. The blood Wassermann was four plus. Nose and throat cultures were negative for Klebs-Loeffler bacilli., and the throat was negative to inspection. The rather characteristic clinical features at once made the diagnosis of congenital syphilis obvious.

LARYNGEAL DIPHTHERIA.

By far the most common error in the diagnosis of this condition in children up to the age of three years is that of confusing it with bronchopneumonia. We have seen innumerable instances in which this mistake has been made. The dyspnea, croupy cough, and retractions in cases of bronchopneumonia in these youngsters, are due in a majority of cases to bronchial and tracheal obstruction by large plugs of mucus. Many times the child may cough up a portion of the mucus, which is mistaken for diphtheritic membrane. An important point to bear in mind in this connection is that these children, when intubated, seldom react well. Instead of a cessation of the dyspnea and retractions and a return of the normal color, the difficulty in breathing persists, due to the fact that the obstruction is low down, past the tip of the tube. When the tube is withdrawn, there is usually a large amount of mucus filling the lumen. Laryngoscopic examination in these cases is usually conclusive.

The signs elicited by auscultation are frequently vague and indefinite. The stridor plays an important part in confusing the examiner, and it is a rather difficult feat to select from the medley of adventitious sounds typical tubular breathing. Where there is a moderate amount of consolidation, percussion is of greater value from the viewpoint of diagnosis. However, it must not be forgotten that bronchopneumonia is a common and early complication of laryngeal diphtheria, and on many occasions we have found it present shortly after the onset of the disease.

Retropharyngeal abscess frequently presents a clinical picture with all the features of laryngeal dipththeria, and we have observed many cases in which this was the prevailing condition, but which had been diagnosed croup. This type of abscess is common in children up to the age of three, and especially in infants under one year. In early cases in which the mass has not attained any considerable size, the respiratory sounds are not characterized by marked stridor, as in laryngeal disease, but are rather of a gurgling type. Respiration through the nose is usually obstructed, the head is thrown back, and there is considerable snoring during sleep. There is usually a rise in temperature, associated with moderate constitutional reaction, such as vomiting, anorexia and not infrequently prostration to a marked degree. An accurate history in these cases is highly important. In cases, however, in which the abscess has developed rapidly the respiratory symptoms are much more marked and may closely simulate diphtheritic croup. The stridor is accentuated, there are well marked retractions of the interspaces, some degree of cyanosis, cough, and well marked constitutional reaction. Palpation of the pharynx will in most cases reveal a mass along the posterolateral wall, projecting forward. Fluctuation may or may not be present, depending upon the stage of development. Occasionally the mass burrows downward so that it may be seen externally on one side of the neck behind and below the angle of the jaw. Incision by means of a bistoury and evacuation results in an almost immediate cessation of respiratory difficulty.

A foreign body in the larynx may present symptoms of a nature similar to laryngeal diphtheria. This is characterized by a sudden attack of paroxysmal cough, dyspnea, hoarseness, and sometimes bloody expectoration, with an absence of fever. The history is of great significance. We mention this condition as an important element in the differential diagnosis. It is, fortunately, not a common error. The differential points of acute spasmodic laryngitis have already been discussed.

Laryngismus stridulus, enlarged thymus, and laryngeal papillomata may present respiratory symptoms simulating croup, and these conditions should be considered in the differential diagnosis, especially in younger infants and children. The characteristic feature of these, however, is the very sudden onset with extremely severe respiratory difficulty. Papillomata, when attaining considerable size, may completely occlude the larynx, giving rise to sudden signs of suffocation. Laryngoscopic examination will reveal the presence of these growths. These latter conditions have not frequently been misdiagnosed, but they serve to emphasize the importance of complete laryngoscopic examination in all cases which are veiled with a curtain of doubt.

The foregoing conditions comprise the possibilities for diagnostic error in the cases of laryngeal diphtheria met with in infants and children. In reverse order, there are several conditions in adults which are frequently misinterpreted and diagnosed croup. Since this is a comparatively rare condition in adults, we are always suspicious when such cases are sent in.

Three conditions are to be borne in mind in this connection, namely, tertiary syphilis of the larynx, tuberculous laryngitis and malignancy of the larynx. Spielberg (2) states that the first mentioned condition may attack the larynx in the form of a gumma, as an ulcerative process, or in the form of perichondritis or necrosis. He mentions further that dyspnea may take place gradually or suddenly, as in the case of edema with too rapid encroachment on the glottic space. It is easily apparent that a malignant growth developing rapidly and finally obstructing the lumen of the larynx could give a syndrome essentially resembling the onset of laryngeal diphtheria.

SCARLET FEVER.

This disease, when appearing with all its typical features, is not difficult to diagnose. It is perhaps unfortunate, however, that so many of the textbooks lay such particular stress on the typical symptoms and signs, considering the atypical pictures of minor significance. As a consequence, those inexperienced in contagious diseases hesitate to make a diagnosis unless the case presents itself as conforming to the textbook description. As a matter of fact, in a large number of instances, this disease presents a variety of atypical clinical syndromes, leaving room for a wide range of error in diagnosis. The rash is perhaps responsible for a large number of mistakes, since there are many factors entering into the production of a typical scarlatiniform erythema. These we shall refer to presently.

The typical case presents four cardinal symptoms: 1, a congested throat, varying in intensity; 2, a red coated tongue, with raised papillæ—the socalled strawberry tongue; 3, fever, ranging from 102 to 105 degrees; and 4, the rash punctate, erythematous. Sore throat, headache and vomiting are commonly associated features. The pulse is rapid, there is a moderate degree of prostration, and glandular enlargement. The onset is sudden, varying in character in children, in whom convulsions are a common initial symptom. Circumoral pallor is visible depending upon the intensity of the flush on the face. From the viewpoint of diagnosis it is of minor importance. The rash presents a number of variations, all of which are within the limits of the typical case. The color varies from a pale red to that of a boiled lobster, and sometimes to a dusky red. It may appear in blotches, leaving many free areas, especially on the extremities. In many instances it assumes a vesicular character (scarlatina miliaris). There is usually some exudate in the throat, probably of a streptococcic nature. These are the essential features of the ordinary case of scarlatina. We shall not discuss the course of the disease nor its complications, as we are concerned here only with the clinical signs and symptoms and their significance in diagnosis.

Early in the disease, before the eruption has appeared, it is not uncommon to have the streptococcic exudate in the throat interpreted as a diphtheritic membrane, and a diagnosis of diphtheria made. The following case illustrates this error.

Case VII.—A boy of six years was admitted with a diagnosis of diphtheria. He had a bilateral cervical adenitis, the throat was congested, the tongue was coated, with a red tip and prominent papillæ. A small whitish patch of exudate was seen on each tonsil. The temperature was 103°, and a faint erythema could be seen over the body, to a less extent over the extremities. He was placed in isolation, and the following morning a typical punctate, erythematous rash appeared over practically the entire body. The throat symptoms were accentuated, the tongue was characteristic, and there was a fairly well marked constitutional reaction. The entire clinical picture at once made it apparent that we were dealing with a scarlatina. The exudate on the tonsils had, in this case, been responsible for a diagnosis of diphtheria. A consideration of certain characteristic differential points might have resulted in a correct diagnosis in this instance. In the first place, in a large proportion of cases of early scarlet fever, the throat presents a greater degree of congestion than in diphtheria, and there is invariably a greater or less amount of exudate distributed over the tonsils and the posterior pharyngeal wall. It is of a mucoid consistency, and does not have the conformation of a true diphtheritic membrane. Again the degree of pyrexia is usually higher than in diphtheria, and the tongue is characteristic. Lastly, the presence of a definite angina, a high fever, a history of headache, sore throat and vomiting, together with suggestive blush over the body, should at once suggest scarlet fever. It is safe to make such a diagnosis tentatively, watching the case closely for the development of a more characteristic rash. However, in the absence of fairly well marked symptoms, and in the event of doubt as to the true nature of the exudate, a safety first measure in the form of antitoxin is always indicated. By far the greatest source of error in the diagnosis of scarlatina is the scarlatiniform eruption. A toxic rash may simulate all its essential features.

THE INTERPRETATION OF RASHES.

The interpretation of a skin eruption suggesting one or more of the acute exanthemata is often difficult, partly because of the presence, in many cases, of confusing clinical symptoms, and partly because of the many conditions which may produce eruptions resembling them. A brief discussion of these will perhaps emphasize the points to be considered in the differential diagnosis, besides illustrating some common errors.

Certain drugs, when taken over a long period, not infrequently produce eruptions simulating measles or scarlet fever. Chief among these are antipyrine, copaiba, chloral, cubebs, bromides, the salicylates and belladonna. It is therefore apparent that a careful inquiry regarding medication is important in ascertaining the underlying etiology of the prevailing eruption.

Serum rashes are another source of confusion, and we have seen this well illustrated in cases of diphtheria, following the administration of antitoxin. These eruptions may be classified into, 1, the scarlatiniform; 2, the morbilliform, and 3, the urticarial. The first presents all the features of a true scarlatinoid rash; the second simulates measles; and the last is characterized by the formation of wheals commonly seen in urticaria. The time of appearance of the rash varies, the limits being from one day to several weeks. A careful analysis of the associated symptoms and signs, together with a knowledge as to whether or not any serum has been injected, is of the utmost importance in sidestepping a diagnostic pitfall.

Erythema scarlatinoides.—This is a condition characterized chiefly by a diffuse erythematous rash conforming closely to that of scarlatina. Scholz (3) states that a differential diagnosis of scarlatinoid erythema from scarlet fever cannot be made on purely dermatological grounds, but only on the clinical associated symptoms. Even then it can be done only in typical cases. The accompanying constitutional symptoms in scarlet fever form the chief guide in diagnosis. A simple scarlatinoid erythema presents none of the symptomatic features of scarlet fever, except occasionally a rise in temperature. Furthermore, desquamation appears within twenty-four to forty-eight hours following the rash. While it is true that in many cases of scarlet fever there is a primary desquamation occurring within three to five days of the full development of the rash, the clinical picture associated is the guidepost in diagnosis.

Scarlatiniform type of rubella.—This type of rash often leads to confusion, as it closely simulates that of scarlet fever, but here again the intensity and character of the symptoms and signs come into play. In rubella the constitutional reaction is mild, the throat and tongue are negative, and there is little or no fever. The rash appears on the face and spreads downward, while the color is inclined toward a coppery hue rather than the pink blush of scarlatina.

Erythema infectiosum.—In this condition the rash appears first on the face in the form of a reddish efflorescence, symmetrically distributed especially on the cheeks, and bearing some resemblance to erysipelas. On the second day the eruption spreads over the body, being especially well marked over the gluteal region and the outer surface of the arms and legs. The trunk is involved only to a limited extent. It is morbilliform in character, more macular than papular, and, when fully developed, may resemble the eruption of rubella. The latter, however, is characterized by uniform distribution over the entire body, discrete, macular, and sometimes confluent. It is further characterized by its short course and duration.

Extensive erysipelas.—This sometimes resembles the rash of scarlet fever, but is differentiated by the sharp line of demarcation and the dusky, indurative appearance. It has no punctate character and the boundaries of the areas involved are sharply defined.

Milaria vesiculosa.—Scarlatina miliaris is rather closely simulated by milaria vesiculosa so that it is not uncommon to have these conditions confused. The former, however, is often associated with intense itching and burning, and has none of the characteristic symptoms and signs of scarlatina. The attending lesion consists of multiple vesicles situated on a red base, followed in a few days by a fine desquamation.

Eczema.—Certain forms of eczema, notably a diffuse type involving extensive areas and of an inflammatory, erythematous nature, may cause confusion at times. However, the severe itching associated with this condition, with the absence of the characteristic features of the exanthemata, will usually place one on the right path of diagnosis.

We have briefly outlined some of the skin eruptions which sometimes lead one into erroneous diagnosis with regard to the exanthemata. It is quite apparent that a careful study of all skin manifestations is essential for thoroughness in diagnostic methods relative to the contagious diseases. We shall discuss the differential points regarding the lesions in varicella and variola in the description of the chemical pictures of these diseases.

PERTUSSIS.

The symptoms and signs of this disease usually follow a typical course. There are, however, cases in which the train of symptoms present some atypical features, so that the diagnosis cannot readily be made. Again there are certain symptomatic variations which strongly suggest the prevalence of some other disease, leading in many instances to a wrong diagnosis.

The catarrhal stage of this condition is ordinarily characterized by the symptoms of a tracheobronchitis, such as cough, hoarseness, coryza, fever and malaise. There may or may not be definite signs in the chest. Usually a few scattered râles may be heard. It is during this stage that laryngeal irritation not infrequently gives rise to a croupy cough similar to that of a laryngeal diphtheria. Here again, in the event of doubt, the laryngoscope settles the question.

Pertussis in infancy offers a difficult problem in diagnosis, since frequently they are few typical symptoms, the paroxysmal cough invariably being absent. Griffith (4) states that in severe cases in infancy the occurrence of cough without whoop but followed by attacks of apnea is strongly suggestive of pertussis. This is well illustrated by the following case:

CASE VIII.—A male infant of five months (admitted at another hospital) was brought in by the mother, the chief complaint being cough followed by periods during which the child did not appear to breathe. Examination revealed a well nourished infant, apparently comatose. The periods of apnea were well marked, followed by short, feeble coughing, not paroxysmal or whoopy. Cyanosis followed each attack of coughing, the normal color returning after the attack. These were the only characteristic symptoms. History brought to light the fact that the child had been exposed to whooping cough, the mother stating that an older child had recently had the disease. On the basis of this and the peculiar type of cough, a diagnosis of pertussis was made. Treatment was of no avail and the child died on the following day. Autopsy showed a bilateral basal pneumonia, which was a complication of the primary condition.

VARICELLA AND VARIOLA.

The differential diagnosis of these two conditions is not always a simple matter, and it is often difficult to ascertain which one we are dealing with. There are, however, certain characteristics attending each, which, if carefuly noted, will obviate many errors in diagnosis. The former is a disease common to infancy and early childhood, the latter to adults. In varicella the constitutional symptoms are slight, while in variola they are of a varying grade of severity. The essential features of the eruption of the former are: 1, that the lesions appear in crops; 2, the rash makes its appearance first on the face and back, less often the limbs; 3, the lesions are most numerous on the back and trunk, but attack all parts; 4, because of the appearance in crops, the lesions may be seen in all stages of development, from macule to crust. In the latter, the lesions go through an evolution covering a period of eight to nine days; the first lesion is a red macule, which becomes papular, vesicular, and pustular as the disease progresses; the vesicles are multilocular; the pustules assume a globular form, without umbilication; it may remain unruptured, with a secondary umbilication developing. The face and wrists are the first sites of attack, extending to the hands, head and arms, and lower extremities, reaching its height of development in about twenty-four hours. The trunk is the least involved. The lesions may also be found on the mucous membranes of the mouth, pharynx, and nose. Desquamation appears about the twelfth day of the eruption.

Impetigo contagiosa sometimes resembles varicella, but the irregular distribution of the lesions, due to autoinoculation, is a distinctive differential point. The lesions are generally discrete, and involve the scalp, face and hands primarily. There is little itching and practically no constitutional symptoms.

MUMPS.

There are several conditions which may simulate acute epidemic parotitis, serving as sources of error in diagnosis. Acute cervical adenitis is a common one. In this condition, however, the swelling is most marked below the jaw, while in mumps it is just in front of the lobe of the ear. The course of adenitis is more prolonged, and there is likely to be more of a constitutional reaction. The swelling is also more tender.

A secondary parotitis developing in the course of other diseases such as typhoid fever, is unilateral and has a tendency to suppuration. It is not uncommon to have diphtheria diagnosed as mumps because of the extensive adenitis. The throat symptoms, however, are conclusive. An infected molar tooth many times causes marked swelling which is often mistaken for mumps. Careful dental examination will usually reveal the true condition.

The purpose of this paper has been to present some common errors met with in dealing with the acute contagious diseases, so that some idea may be had of the numerous sources of error, the behavior of atypical cases, and the diversity of clinical pictures which might easily lead one astray. The large number of cases seen at this institution has afforded us ample opportunity to note particularly the relative frequency of diagnostic error, the types of mistakes commonly made, and the proportion of cases with atypical syndromes. We have made no attempt to go into detail regarding the differential diagnosis of these diseases, but have rather limited ourselves to a discussion of the variety of errors met with. The diagnosis of contagious diseases in atypical forms is by no means an easy matter, and it is with the purpose of stimulating greater care in the analysis and interpretation of symptoms and signs that we have presented these case reports. Infallibility is a superhuman virtue which none of us can hope to possess. Carelessness and laxity of methods, however, are traits of which too many of us are guilty. It is, therefore, more in the nature of a plea for better care and methods in diagnostic work that we have outlined these cases, which in themselves are argumentative. A great artist, when asked how he mixed his colors to obtain such wonderful effects, replied: "with brains, sir!" The point of which is obvious as applied to diagnostic work.

The Rapid Cure of Cystitis in Children

By JOHN COOKE HIRST, M.D.,

Philadelphia, Pa.,

Chief Obstetrician to St. Agnes' Hospital.

Every physician is familiar with the distressing symptoms of acute cystitis and pyelitis in female children. Fortunately relief can be secured very quickly, in many cases after one treatment only, and the contrast to older methods of palliative treatment is very marked.

The symptoms need little consideration, except upon one point to be mentioned shortly. The very frequent urination, violent tenesmus and spasm, the cloudy urine loaded with pus cells, leave no possible doubt as to the correct diagnosis. The most common infecting agent is the colon bacillus and the vagina is often infected as well. This naturally causes considerable redness and edema of the labia and vaginal mucosa and a fairly profuse yellow purulent discharge. I have been struck by the frequency in which, in my consultation practice, a diagnosis of gonorrheal vulvovaginitis has been made in these cases. The diagnosis has been based entirely upon the discharge and its color, in spite of the fact that no gonococci have been found, and much valuable time has been lost in treating the patient on this mistaken basis, naturally without favorable result. I cannot too strongly urge the prompt recognition of the true nature of the infection and the avoidance of a diagnosis of gonorrhea simply because the child has vulvovaginitis and a profuse yellow discharge.

The proper treatment is astonishingly simple and easy and in my experience invariably rapidly effective. It consists in the injection into the bladder of five c. c. of a ten per cent. solution of silvol or neosilvol, to be retained if possible. The retention of the solution seems to be of secondary importance, however. In very young children it will promptly be evacuated, but enough seems to remain in the vesical base to secure the desired result. It is very unwise to use more than five c. c. at a time, as a larger quantity is sure to be expelled, and any chance of retaining it will be lost. Silvol makes a solution strongly resembling argyrol, and has the same happy faculty of staining everything it touches a deep brown. Neosilvol makes a turbid yellowish solution, is equally effective, and does not stain at all. For this reason I employ the neosilvol solution routinely, although it does not keep as well as the silvol and should, therefore, be prepared in small quantities. It is undeniably better, though somewhat troublesome, to prepare the solution fresh for each treatment, although for a week or two the neosilvol stock solution shows no sign of deterioration. These silvol salts are so far superior in their results to any other I have used that I now employ them routinely for all bladder or kidney pelvis irrigations.

TECHNIC.

1. The child is arranged in the dorsal lithotomy position, and its knees held apart by an assistant or nurse.
2. Anesthesia will occasionally be required, because of the child's unruliness, and not because of any pain caused by the manipulations. Light ether or chloroform anesthesia is all that is needed, for a few seconds only.
3. A small soft rubber catheter is boiled and inserted into the bladder, after proper preliminary sponging and cleansing of the vulva.
4. Urine in the bladder is allowed to flow out.
5. No irrigation of the bladder is required and it is a waste of time to do it.
6. Through the catheter is injected, by a piston syringe, five c. c. of ten per cent. silvol or neosilvol solution, and the catheter quickly withdrawn.
7. In most cases the solution will be retained from fifteen minutes to several hours. The younger the child the more likely the shorter retention. Even if it is passed at once, sufficient residue will remain to do the work. It is not necessary immediately to repeat the injection, as it will only be evacuated again, more promptly than before.

RESULTS.

In most cases the results are immediate. The tenesmus promptly ceases, the frequency of urination diminishes or disappears, and the child is immediately comfortable and quiet. If the symptoms recur or the urine does not promptly clear, the injection can be repeated. I have found this rarely necessary, however, in the acute cases. In older girls of six or seven, who have had cystitis of long standing, with occasional exacerbation, repeated injections are often necessary, but in the acute cases, especially if no time has been wasted on medicinal or mistaken treatment, the results are prompt and satisfactory.

The age of the child has no bearing whatever on the practicability of the injections. The urethra of a female child is surprisingly distensible, as is well known, and no difficulty will be encountered. I have carried it out in an infant one month old, without trouble. In babies, of course, the ability to retain the solution is a matter of luck, and its prompt evacuation need not cause any concern.

The results have been so uniformly successful that a couple of illustrative histories will suffice to show the reaction to be expected.

CASE I.—A little girl, two and a half years old, was brought to me suffering with vulvovaginitis and cystitis. She had violent tenesmus, very great frequency and would scream with pain whenever she attempted to empty the bladder. This condition had been present with varying severity for over two months. Because of the vulvovaginitis, gonorrhea had been diagnosed, and the child treated accordingly, without benefit. The bladder was injected with ten per cent neosilvol solution, which was evacuated after a few minutes' retention. No attempt was made to repeat the injection at that visit. The mother reported that the child slept better that night than for several weeks, but still had some tenesmus and frequency. The next day the injection was repeated at 3.30 p. m. The child retained the solution until 7.45 p. m. when it was evacuated without pain. Frequency and tenesmus ceased, and she slept all night. These symptoms did not return. In three days the urine was microscopically free from pus, and the child perfectly well. There has been no recurrence of the cystitis.

CASE II.—A little girl, aged two years and nine months, had had cystitis for over four weeks. Very frequent urination and great tenesmus. The frequency at night was so great that sleep was impossible. There was no accompanying vulvovaginitis, and the child had been treated for four weeks, upon a proper diagnosis, with only slight benefit. She was very much frightened and unruly and light ether anesthesia was needed to enable me to catheterize her. She was anesthetized, partially only, for a few moments. Eight c. c. of freshly prepared ten per cent. silvol solution was injected in the bladder, at 7.15 p. m. To my surprise this was retained until 11.30 p. m. without evidence of discomfort. It was then evacuated without pain. She slept all night, except for one painless urination at 4.30 a. m. The tenesmus, frequency and pain had all disappeared the next morning. The urine showed pus, microscopically, for three more days, and was then free and has remained so. The child was symptomatically well within twelve hours of the injection and was comfortable immediately. Only one injection was needed.

The case histories reported are by no means exceptional. I have learned to expect immediate favorable results, and have no faith whatever in the so-called palliative treatment. These injections are easily made, require no special skill and the instruments required are in the possession of every physician in the land. I feel very strongly that, if in these cases of acute cystitis the bladder is immediately drained and the solution injected, the favorable results will be prompt and an incalculable amount of suffering will be saved these children, not only at the time of the attack, but in later years, by preventing the establishment of a chronic cystitis, at that time much more difficult to control.

Acute cystitis is much more common in female than in male children. My work deals entirely with the female child and I have had no experience with the male. I see no reason, however, why it could not be as successfully treated, the sole difference being the greater difficulties of catheterization.

1823 PINE STREET.

Acute Mastoiditis with Facial Paralysis and Remittent Meningitis*

By A. ROTH, M.D.,
Brooklyn, N. Y.,
Associate Laryngologist to the Jewish Hospital, Brooklyn; Attending Otolaryngologist to the Beth Moses Hospital.

This case of otitic meningitis is reported because of its unique clinical course.

The patient, a robust man of twenty-eight, presented himself to me on the third day after the appearance of the initial symptoms of acute otitis media. Examination disclosed the classical evidences of acute osteomyelitis of the mastoid process. He was admitted to the Brownsville and East New York Hospital the same evening and an operation was to be performed in the morning. On my visit to his bedside before operation I was surprised to find that a complete facial paralysis on the side of the disease had developed since he entered the hospital.

On opening the mastoid I found a rather extensive destruction and it was necessary to remove the whole tip. But the sinus plate and the bony roof of the mastoid and tympanic cavities were not involved and there was no evidence of exposure of the facial nerve in the posterior wall after complete removal of the diseased structure.

Ten days after operation the facial nerve had entirely recovered its function and there was no sign of paralysis, and the patient was discharged from the hospital in excellent condition. For nearly six weeks thereafter he came to my office for dressings and had never complained during this period. The wound was nearly closed when the patient began to experience pain in the same ear and in the right side of the head. After three days of careful observation, the symptoms becoming even more acute, I sent him to the Beth Moses Hospital where I was on service.

The clinical data of the next two days were as follows: temperature between 99° and 103°; headache more diffuse; eyegrounds normal; general neurological examination negative; blood culture found sterile. In view of the increasing severity of the symptoms, however, I reoperated for exploratory purposes, this time deliberately uncovering the whole course of the sigmoid sinus. This exhibited no pathological changes whatsoever. The bony roof of the mastoid and middle ear was solid and free from any carious process. There were no fistulæ; no areas of disease were discoverable. From an exploratory viewpoint the operation was valuable in that it eliminated the mastoid itself as the seat of the present trouble. It seemed advisable to give further study to the case before removing the mastoid roof.

The patient was closely observed during the next two days; examination of the cerebrospinal fluid proved normal; the laboratory gave no clues; the headaches continued with the same severity and the man was becoming exhausted. Therefore, I decided to expose the middle and posterior fossæ. Extensive removal of the tegmen of the mastoid and middle ear, thus exposing the temporal dura, revealed no pus. The posterior fossa was then exposed in the small space situated between the anterior border of the sigmoid sinus and the external semicircular canal and no epidural abscess was located here. The appearance of the dura in both anterior and posterior fossæ was normal. There were no focal signs of cerebral abscess. Logically there was no alternative but to dress the wound and to await developments.

We were pleasantly surprised following this operation to see a rapid improvement beginning on the second day, the patient being discharged in good condition at the end of ten days. The relief of symptoms might be attributed to the decompression, and the effect which this had was suggestive of a localized irritation of the meninges or even of a circumscribed intradural suppuration which remained limited and quiescent. He came to my office again for dressing, feeling well and never complaining, for two weeks. At the end of this time he took ill quite suddenly with violent headaches and chills and I was called to the house where I found the glaring signs and symptoms of acute meningitis. He was admitted to the hospital the same day. The spinal tap proved the presence of decidedly cloudy fluid.

Four days' study gave us no differential clue as to the existence of the meningitis in sympathy with a cerebral abscess, or whether the sudden manifestation of meningitis was a primary intracranial complication. The questions were logically connected with the period of remission between the decompression operation and the sudden and definite signs of meningitis. There were no bacteria demonstrable in the cerebrospinal fluid at this time and there were no focal signs. The patient was becoming progressively worse. His only chance was the exploratory incision of the temporal lobe and of the cerebellum for possible abscess which in either region might readily exist without local symptoms.

I therefore explored the temperosphenoidal lobe and the cerebellum, and found no pus. The probability of an initial intracranial involvement in the form of a circumscribed meningitis became a more palpable diagnosis of the case, the infection having been carried along the facial nerve sheath at a time prior to operation or during convalescence, the nerve itself receiving the organisms primarily with the acute mastoiditis, through anomolous openings which are known to exist at times in the facial canal and which in this case must have been present in this canal in the region of the posterior wall of the middle ear: or perhaps the corda tympani branch of the facial first became infected.

The sudden manifest meningitis is explainable by the breakdown of the limiting adhesions and the entrance at once of the infection into the subarachnoid space. Repeated examinations of the cerebrospinal fluid finally showed the presence of the Streptococcus mucosus capsulatus. The patient died one week after operation. Autopsy was not obtainable.

Diligent search through the literature failed to reveal the record of a similar case. This case had an uncommon feature in the occurrence of facial paralysis with acute mastoiditis, and a unique feature in the remission of a meningeal process of otitic origin.

The Value of Percussion in the Early Diagnosis of Lobar Pneumonia in Children

By JOSEPH POPPER, M.D.,

New York,

Adjunct Attending Pediatrist and Director of the Infant Welfare Department, Lebanon Hospital.

It would seem at first glance somewhat superfluous to broach the subject of the physical signs of pneumonia in children at this late date in the development of physical diagnosis. However, Mackenzie has well said that "it is one of the curious matters in medicine that the commonplace and selfevident are the things which are most frequently ignored." In this paper, therefore, I do not hope to present anything new but will dwell upon one important method of examination, its elicitation, and interpretation.

In a recent paper my colleague, S. A. Blauner, made the significant statement that "the diagnosis of pneumonia in infancy and early childhood is distinctly by physical signs." This is so true that anyone who has had any experience with the care of sick children will readily appreciate the value of a thorough knowledge of the physical signs of pneumonia. Of even greater importance, however, is the ability to elicit and place a proper valuation on individual signs.

Numerous experiences during the past few years have shown that the diagnosis of pneumonia is often overlooked or if not overlooked is guessed at purely from the clinical aspects of a given case, where a careful percussion of the chest would reveal the one important physical sign, viz., dulness on percussion. The great value of the finding of dulness on percussion in the early diagnosis of lobar pneumonia in children cannot be overestimated; and yet a perusal of many textbooks on pediatrics shows that only a few place any stress on the subject. Furthermore, on several occasions in recent years, the examination of candidates for admission to hospital internship has almost invariably failed to elicit a proper conception of this subject. Small wonder then that a great many practitioners do not percuss a child's chest, or do so in a perfunctory manner and attach no great significance to their findings. I have seen some very excellent physicians use their stethoscopes most diligently but percuss, if at all, very hurriedly and crudely. The reason seems to be that most of us have been educated to look for the high pitched breathing or the occasional telltale râle, whereas I venture to state that, in lobar pneumonia at least, dulness is present long before râles or high pitched breathing. The opposite is undoubtedly true of bronchopneumonia.

The proposition to be discussed here, therefore, may be stated as follows: Given an infant or a young child who is clinically ill, with fever, with or without cough, and who shows on physical examination dulness or dull tympany localized in an area of the chest which is normally vesicular in resonance, a diagnosis of pneumonic consolidation is justifiable. This statement is based not only on clinical bedside experience but has been confirmed many times by x ray photographs. Moreover, recent studies both pathological and röntgenological seem to prove that dulness must of necessity be the first sign of lobar pneumonia in at least the vast majority of cases in children.

Tripier, from a pathological study, and Weil and Mouriquand, and in this country Mason, from a röntgenological study, have shown definitely that in lobar pneumonia the consolidation invariably begins at that part of the lung nearest the pleural surface. They have also shown that the involvement occurs as a conical shaped mass with its base at the pleural surface and the apex directed toward the hilum. Mason, furthermore, has correlated his röntgen findings with the development of physical signs, an extremely valuable contribution. He found that early in lobar pneumonia a shadow appeared at the periphery of the lung without giving any physical signs. Subsequent radiography of the same patient showed an enlargement of the shadow at the periphery and gradual extension of the shadow toward the root of the lung. This enlargement of the shadow coincided with the gradual appearance, first, of dulness over the area involved, and that only relatively dull, followed by increased dulness accompanied by râles and diminished breathing, and finally when the shadow reached the root of the lung, bronchial voice and breathing.

Mason explains this appearance of bronchial breathing and voice by reference to Tyndal's demonstration that sound is transmitted much better through a medium of uniform density than through a medium of varying density. In the case, therefore, of pneumonic consolidation, tracheal breathing can only be transmitted as such to the chest wall when the consolidation is continuous from the trachea or large bronchus to the chest wall.

By this excellent demonstration it becomes quite apparent that the sequence of the development of physical signs in lobar pneumonia must be relative dulness gradually increasing in extent and intensity followed by diminished breathing with or without crepitant râles and finally bronchial breathing and voice. Undoubtedly exceptions to this rule occur depending upon unusual situations of involvement, such as the diaphragmatic surface of the lung and also depending upon concommittant factors like thickened pleura and fluid. Fortunately, however, these exceptions are extremely uncommon.

This offers, therefore, a ready explanation for the contention of my paper. It also explains why bronchial voice and breathing must of necessity come much later in the disease. It likewise explains several phenomena which have until now been erroneously interpreted. Thus we can understand how a lobar pneumonia may go through its entire course without the development of bronchial voice and breathing, the process stopping short of the hilum. It very beautifully explains a term which was until recently and is to some extent in this day used as a cloak for diagnostic ignorance, viz., central pneumonia. We now know why every case of clinical pneumonia was called central in the absence of râles and bronchial voice and breathing. By the same token we can understand how many a diagnosis of prolonged influenza or pyelitis without pus in the urine or other obscure excuses for prolonged fever were very often pneumonia which was overlooked because too much was demanded in the way of physical signs.

If then, dulness must be the earliest physical sign of lobar pneumonia, what is there about the terms "careful" or "proper" percussion which makes all the difference between the presence of consolidation and its discovery clinically? Just here is the crux of the matter, not that there really is a problem for the method of percussion is the same bimanual method in general use. However, three factors are essential to its proper applications, viz.:

1. Light percussion in an atmosphere of absolute quiet.

2. Proper position of the patient. That refers to a position in which muscular resistance is reduced to a minimum. This is best obtained by placing the patient on his back for examination of the front of the chest and prone with the arms extended above the head for examination of the back. The axillæ and sides are examined in both positions.

3. A familiarity with the normal areas of chest dulness. These are the cardiac area on the left side anteriorly; liver dulness on the right side extending from the lower part of the chest anteriorly around to the lower part of the chest posteriorly; and also two areas of impaired resonance, viz., the right apex posteriorly, which is frequently duller than the left, and the left midaxillary region which often gives a dull tympanitic note when the stomach is dilated.

It is also important to emphasize that dulness is a relative term and its intensity will vary with the amount of consolidation present, so that in a given case a diagnosis may be made when an area is discovered which is only slightly duller than the part of the chest immediately adjacent, or as compared to the corresponding area on the opposite side.

Under the head of diagnosis in lobar pneumonia Holt says: "The difficulties in diagnosis are due to the great variation that is seen in the general symptoms, and to the late appearance of the physical signs. The error usually made is to mistake pneumonia for some other disease, rather than to mistake some other disease for pneumonia. On account of its frequency in children, pneumonia should always be excluded before accepting any other explanation of a continuously high temperature." To this I would add, in conclusion, that a mastery of the art of percussion of the chest will establish a diagnosis in the vast majority of the cases of obscure fever in infants and young children.

Typical Quinsy in an Infant

By FRED W. GRAEF, M.D.,
New York.

Acute purulent inflammations of the throat in small children are almost always situated in some part of the wall of the pharynx back of the pillars of the fauces—the socalled retropharyngeal abscess. These are quite common; not infrequent even in very young babies, and as a rule offer comparatively little difficulty in diagnosis or treatment to one accustomed to deal with them. The lax pharyngeal mucosa favors the collection of pus and also the burrowing of such collections in various directions. Marked dyspnea is found as the first urgent symptom in many children and difficulty in taking food with change in the voice is also likely to call attention to the throat. A provisional diagnosis of diphtheria is the most common error in these cases.

Recognition of the mass by the asymmetry of the pharyngeal walls is confirmed by palpation showing the presence of fluid. Often little or no appearance of inflammation about the mass is to be seen. The belief that these abscesses occur mostly in the children of parents with a tuberculous or syphilitic history is not borne out by common experience. They are more likely due to the general tendency to glandular infection and swelling associated with childhood. A short time ago I had a case of throat abscess brought me by Dr. George Krupp, which proved to be a typical case of quinsy and, occurring in an infant only six months old, it seems to me to be of sufficient interest to warrant this report.

The child, a girl, nourished by a combination of breast and bottle feeding, was strong and healthy, and the parents gave no evidence or history of strumous or specific disease. The throat symptoms were of gradual onset but the dyspnea, cough and change of voice had led to a diagnosis of diphtheria when these suddenly became pronounced. The child's mouth was opened with difficulty and incompletely, but examination of the throat showed a typical quinsy of the right side, the anterior pillar bulged forward and the right tonsil pushed well over to the uvula. I had never seen or heard of such a thing in so young an infant, however, and had some hesitation about incising it. When I did cut into it in the usual place a large quantity of pus streamed out and the diagnosis was fully established. It drained and was healed in a few days, very much as such a quinsy would in an adult, without difficulty of any kind.

This was several months ago and I learn from the family physician that the child has had no trouble of any kind since.

I have made some search through available literature and at the library of the Academy of Medicine without finding record of any similar case.

X Ray Studies of Cardiac Diseases in Children*

By W. MORGAN HARTSHORN, M.D.,
and CHARLES WINFIELD PERKINS, M.D.,
New York.

The x ray by means of the fluoroscopic and röntgenographic method in the diagnosis of cardiac diseases, offers valuable assistance in, 1, determining the size, shape, position and action of the heart in relation to the thorax; 2, the condition of the heart muscle; 3, the areas involved; 4, the relative location of the cardiac vessels; 5, the possibility of congenital cardiac disease; 6, the progressive changes in the cardiac muscle as demonstrated through repeated subsequent examinations; 7, indication of associated pulmonary diseases. In the various pathological states of the heart the x ray examinations not only confirm but amplify the clinical findings. The literature in regard to the x ray examination of cardiac diseases in infants and children is at present very limited.

There are two methods of examination, fluoroscopic and röntgenographic. The fluoroscopic method has the advantage of making it possible to examine the patient in every position, besides visualizing the cardiac action and the presence or absence of fluid or adhesions. It is readily adapted for use in very young children.

The plate examination should be made at six feet distance from the tube with the patient in the vertical position during forced inspiration with the breath held. At this distance there is less distortion of the anatomy of the chest. In infants under two years it is practically necessary to make the exposures in the recumbent posture, as rapidly as possible, at a distance of thirty inches. The plate examination gives a permanent record and permits a detailed study of the case.

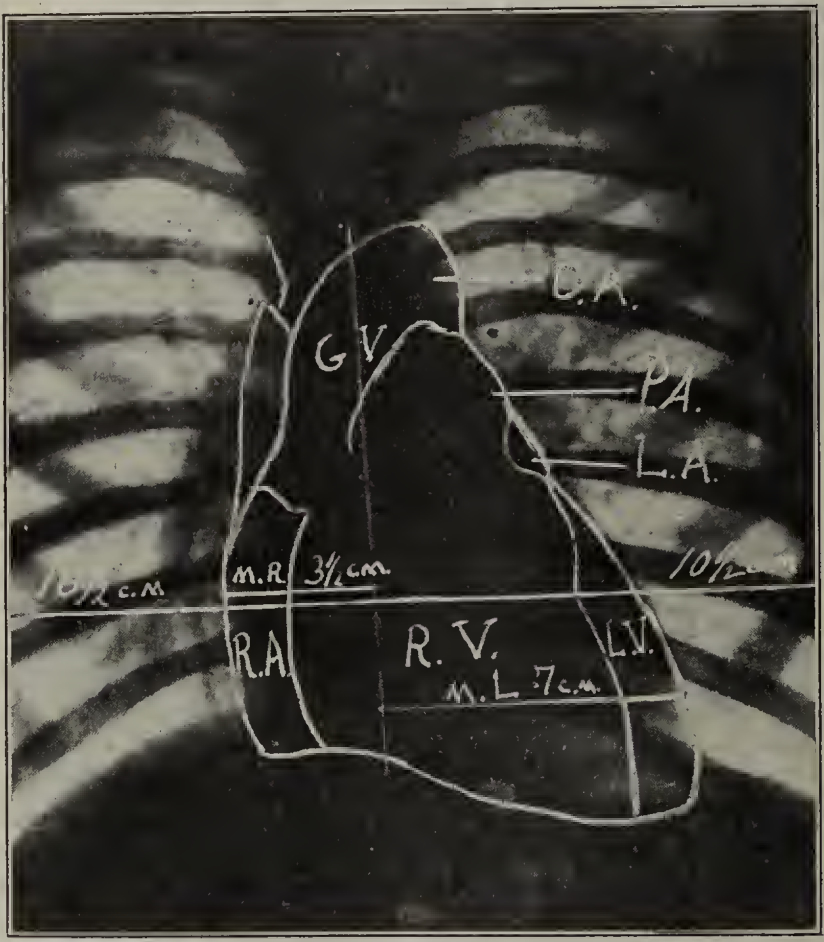

Fig. 1.—Diagram, over a normal heart in a child aged nine years, taken at six feet distance. R. A.: right auricle; R. V.: right ventricle; L. V.: left ventricle; L. A.: left auricle; P. A.: pulmonary artery; D. A.: descending aorta; G. V.: great vessels; M. R.: middle right diameter; M. L.: middle left diameter of the heart. M. R. 3.5 cm. plus M. L. 7 cm. equals 10.5 cm., which is one half the diameter of the chest.

For comparison, a study of the normal size, shape and position of the heart in children is essential. Observations which we have made upon children of different ages from two months to fourteen years show that the size and shape of the heart varies with the size and shape of the chest; for example, a broad-chested child would have a correspondingly broad globular heart, while a narrow chested child would have an elongated heart.

In twenty-one examinations of normal hearts in children whose ages varied from two months to fourteen years, the transverse diameter of the heart through its widest part, equalled or approximated one half the measurement of the chest in a corresponding position. Children under three have a globular heart which appears to be larger than normal, but on measurement corresponds with the findings given above. This measurement is the most important one in the x ray examination of the normal or abnormal heart. It is occasionally found in normal cases that the transverse diameter of the heart is smaller than half the transverse diameter of the chest. It was observed in practically all cases of cardiac disease. While no definite physical signs of involvement of the lungs were found, the x ray examination showed increased peribronchial thickenings, fanlike in character, with intensified linear markings. These were largely confined to the upper lobes of the lungs. Although this condition is sometimes found in normal children in unhygienic surroundings, it is much more pronounced in the patients suffering from cardiac diseases.

Congenital enlargement of the heart has been confused with enlargement of the thymus gland; it is only by röntgen examination of the heart and chest that a diagnosis between these lesions can be made. Distortions of the heart and of the ascending aorta, resulting from imperfect technic in posturing the patient over the plate, should always be considered in making a diagnosis of cardiac and thymic disease.

It is our purpose now to discuss the x ray findings of various pathological lesions of the heart.

CONGENITAL LESIONS OF THE HEART.

This anomaly of the heart is fortunately infrequent, Norris reporting 7.6 per cent. and Still 0.57 per cent. in cardiac cases under ten years. Without clinical findings and the history of the case it would be impossible to make a definite diagnosis of any congenital lesion of the heart from the röntgenograph. In all these the shadow of the heart is enlarged in the right auricular, left ventricular and pulmonic areas. Transposition of the great vessels and dextrocardia, while rare, can be definitely shown by the x ray.

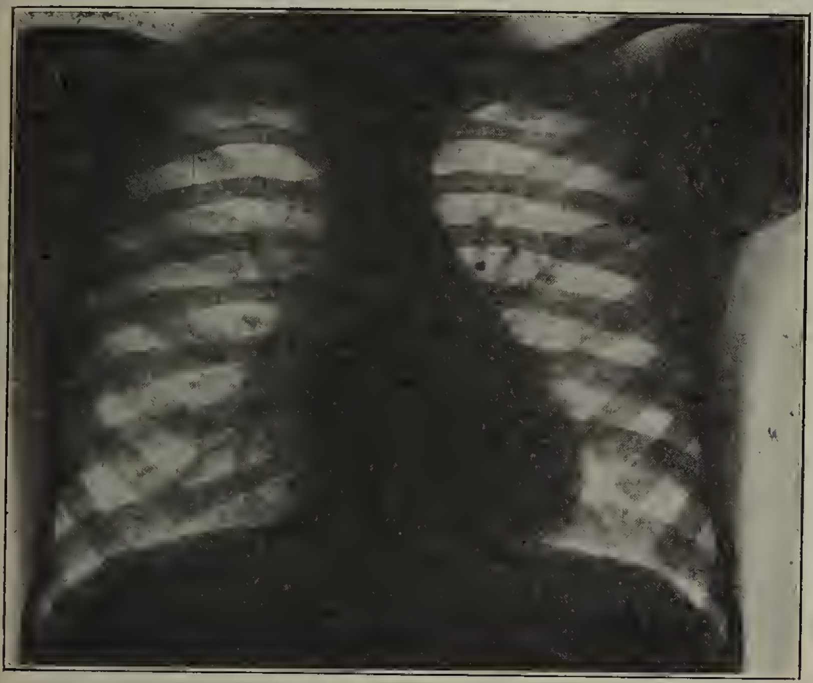

Fig. 2.—Small normal heart of a child aged eight years.

Figures 6 and 7 show the difference between a normal heart and one with congenital lesions at three months, as illustrated by the following case:

Case I.—Baby G., male, three months, was referred by Dr. G. W. Graves, with the following history. The little patient was first seen by Dr. Graves at two months, weight six pounds six ounces. Choking attacks developed when the child was two to three months old, associated with more or less constant dyspnea. There was recession of the suprasternal and infrasternal regions, with moderate cyanosis. Râles were found distributed throughout the lungs several days before the x ray examination. Two days before the x ray was taken there were râles in the right upper lobe anterior chest wall. Percussion was negative. Heart sounds were normal with respiration 40 to 50 a minute. The nutrition improved in one month despite the severe attacks of dyspnea, then the attacks became more marked and on one or two occasions the mother found the baby had ceased breathing and was revived only by mechanical measures. The character of breathing suggested tracheal obstruction similar to that due to obstruction from laryngeal diphtheria. It was noisy but at times moist. Atropine, 1/500 grain, was given every three hours with little effect. Small doses of bromides and ipecac gave some relief. The diagnosis of enlarged thymus was suggested by several consultants, and no other explanation was offered as the cause of the attack, until the röntgenograph re-

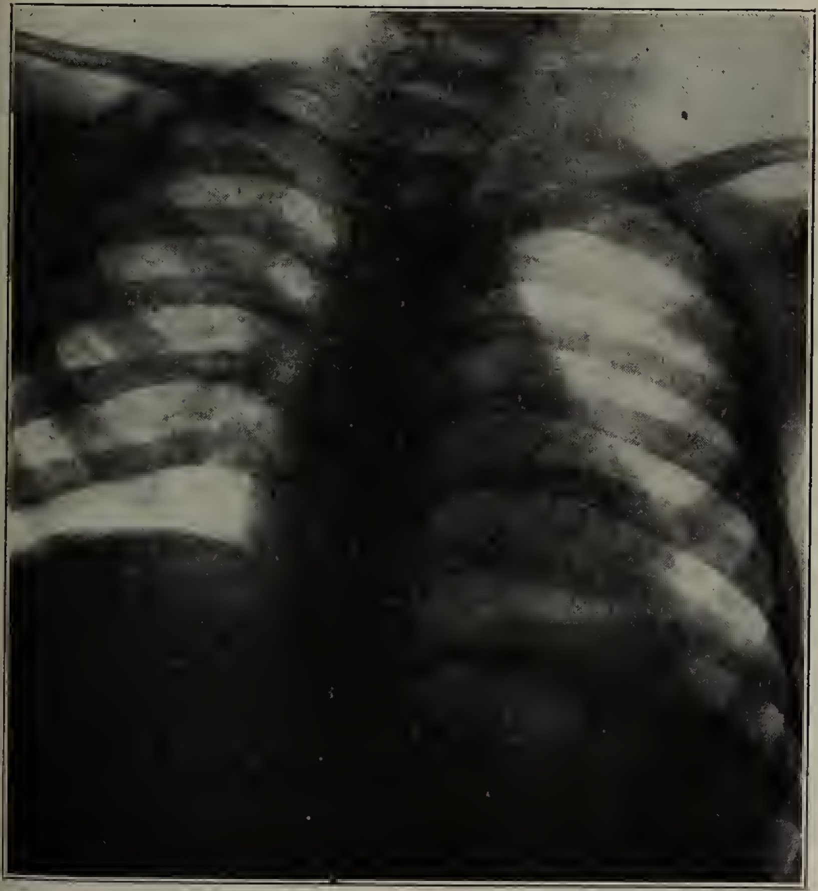

Fig. 3.—Illustrates distortion of heart due to imperfect technic. Normal heart of an eight year old child.

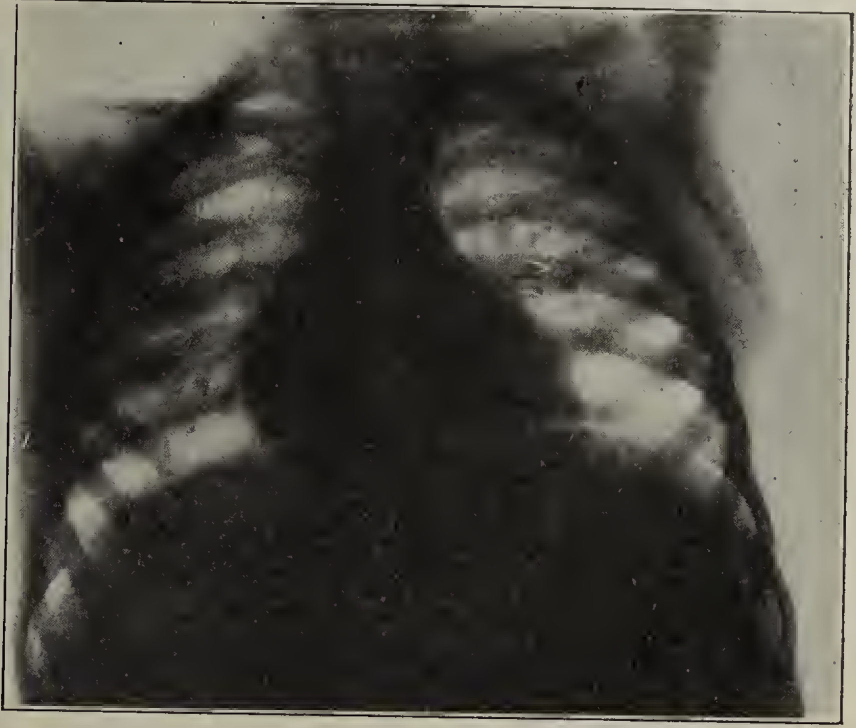

Fig. 4.—Normal heart of child aged two and a half years.

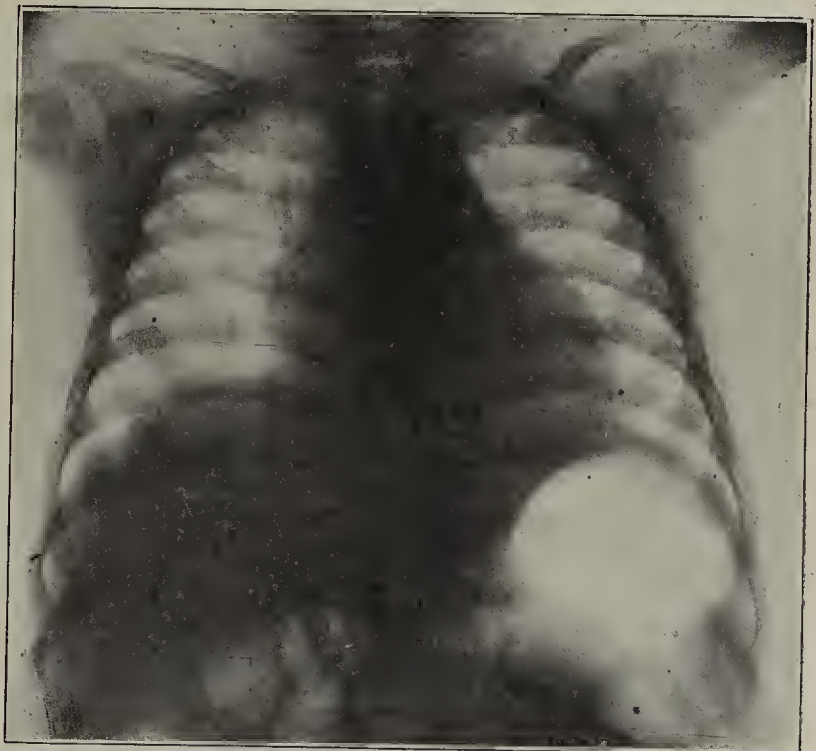

Fig. 5.—Normal heart of an infant aged ten months. Note globular character and broad base.

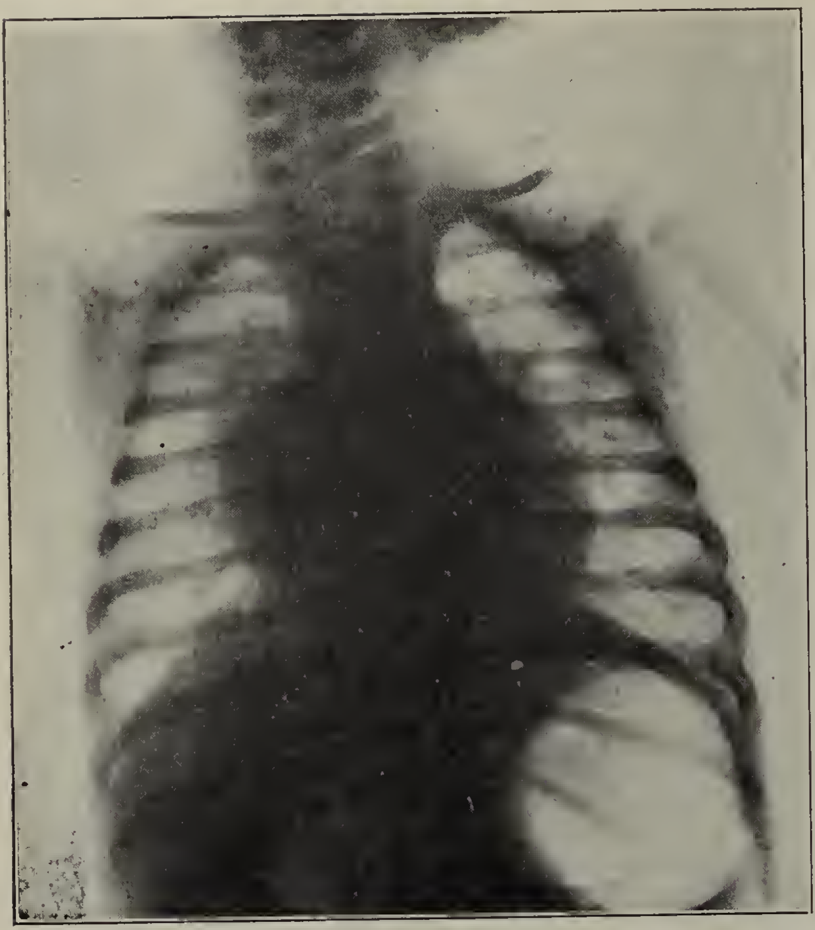

FIG. 6.—Congenital heart of infant aged three months. Note cloudiness of upper right lobe.

vealed the abnormal heart shadow. The baby died three days later. X ray diagnosis was congenital malformation of the heart with bronchopneumonia.

VALVULAR DISEASES OF THE HEART.

Mitral lesions are most frequently found in children as the result of valvular injury. There is marked dilatation with subsequent hypertrophy of the cardiac muscle. This increases the transverse measurement of the heart in comparison with that of one half the chest. If there is also an associated mitral stenosis, as is quite frequent, enlargement of the auricle is present. This is well illustrated by the following cases.

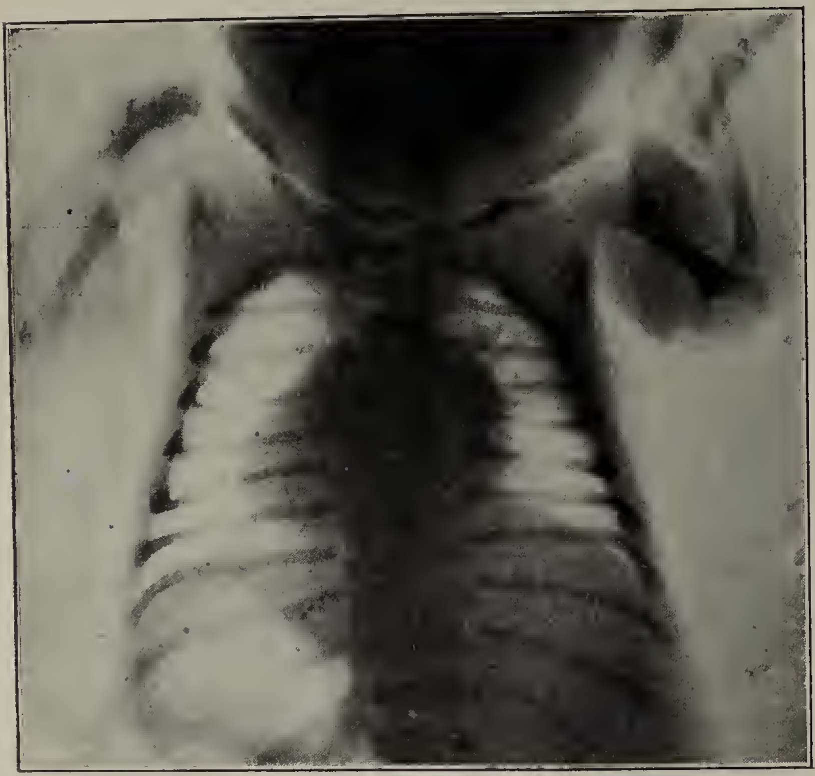

FIG. 6a.—Congenital heart of child aged seventeen days. Very cyanotic. Note cloudiness of the upper right lobe of the lungs.

Figures 8 and 9 show the difference between a normal heart of three and a half years and a pathological heart in a boy of three, suffering from double mitral disease with decompensation. X ray examination at six feet distance showed an enlarged globular heart with enlarged left ventricle and right auricle. The transverse diameter of the heart is three and a half cm. larger than normal. The lungs show a general haziness with evidences of forced respiration as seen in the distention of the chest.

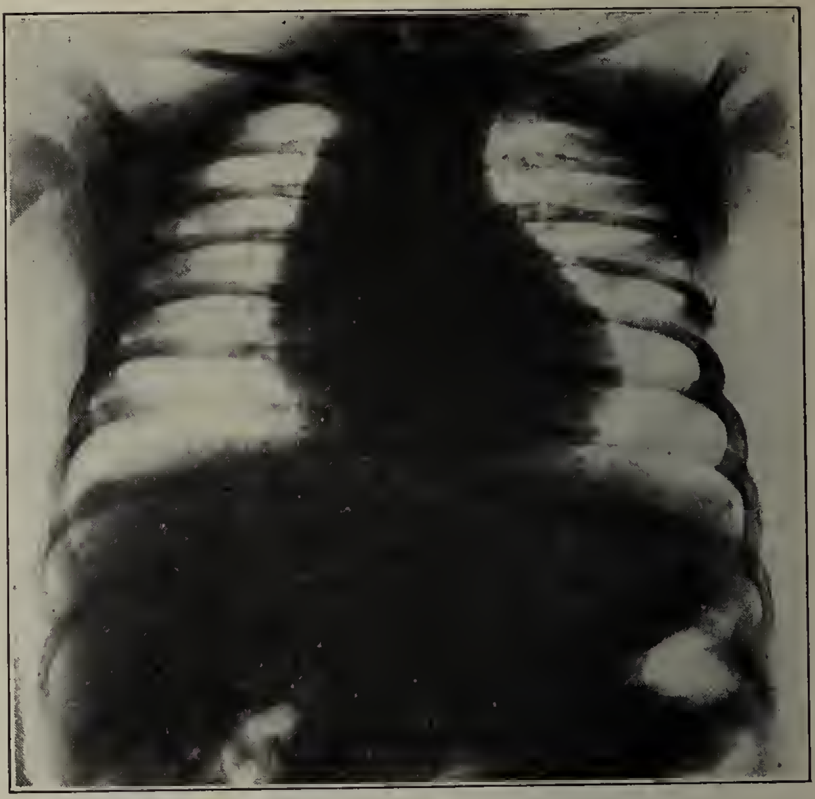

FIG. 7.—Normal heart of an infant aged three months.

Figure 10 shows the heart of a child eight years of age, who entered the hospital with the diagnosis of mitral stenosis and insufficiency. The patient was poorly nourished and slightly cyanosed. Physical examination of the lungs was negative. Heart showed enlargement to the right and left, and presystolic thrill accompanied by systolic and presystolic murmur at the apex.

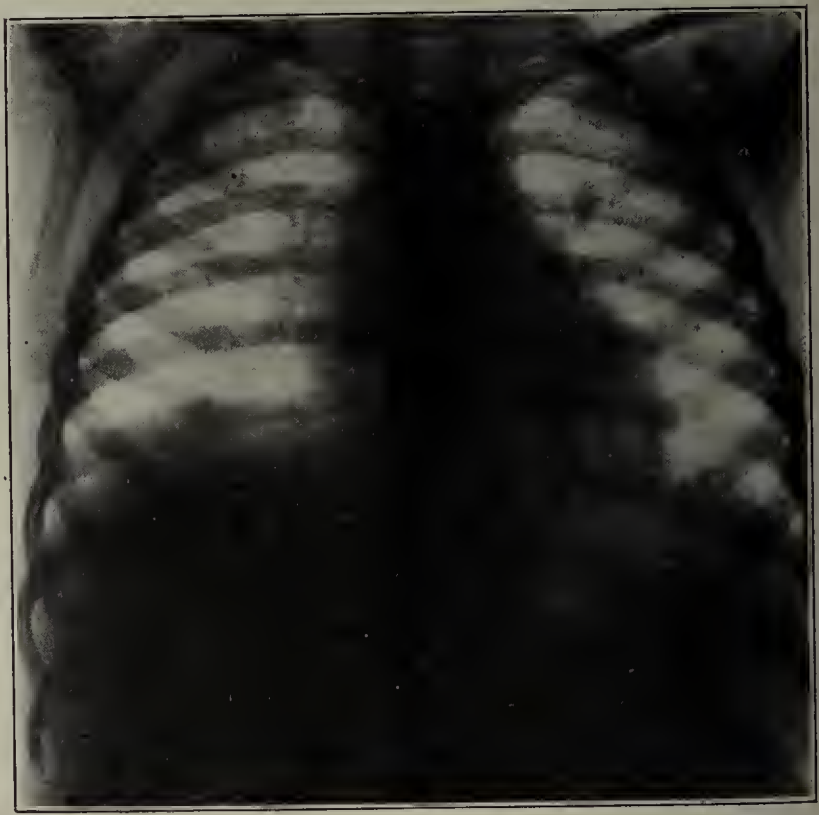

FIG. 8.—Normal heart of a child aged three and a half years.

Teleoröntgenographic examination showed en-

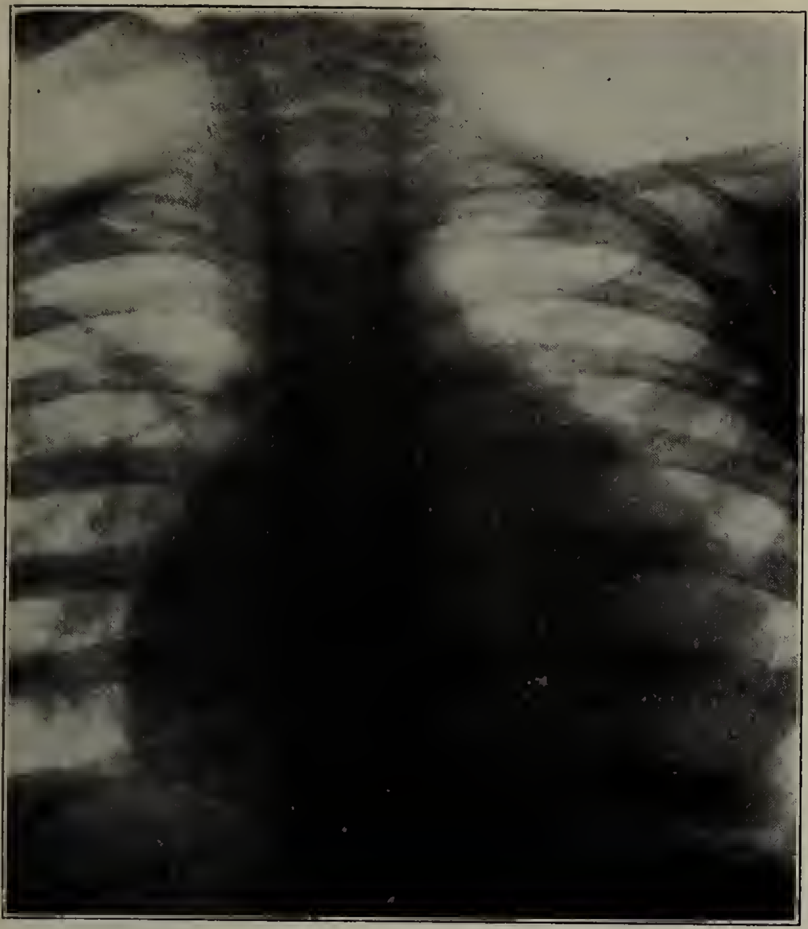

Fig. 9.—Double mitral disease with decompensation in a boy aged three years.

largement to the right and left with the transverse diameter of the heart three cm. larger than normal. The lungs showed increased peribronchial thickenings with linear markings, fanlike in character in both upper lobes of the lungs.

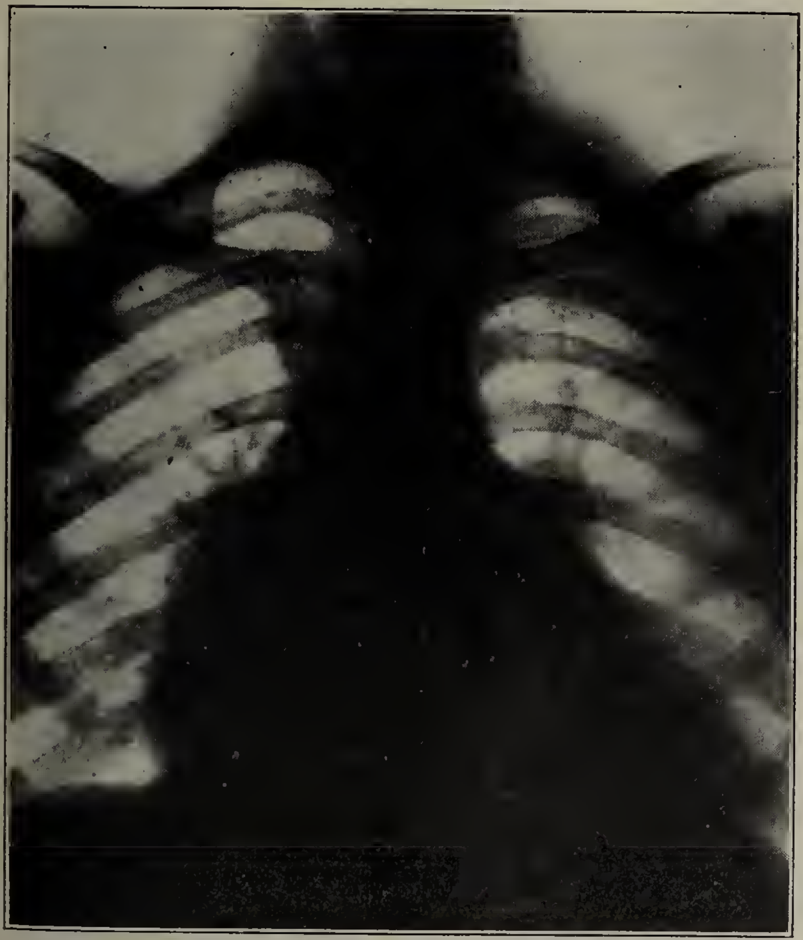

Fig. 10.—Mitral stenosis and insufficiency in a child aged eight years. Note increased peribronchial markings in upper lobes of the lungs.

Figures 11 and 12 show the difference between a normal heart and mitral disease in a boy eleven years old. Examination of the heart showed visible diffuse pulsation over the precordia and neck, with distinct thrill on palpation at apex. Diagnosis was mitral regurgitation and stenosis. The lungs in the left lower lobe presented dullness and râles.

Röntgenographic examination at six feet showed a rounded globular heart enlarged to the right and left four cm. larger in its transverse diameter than normal. The lungs showed haziness in the right middle lobe and base with increased density of the hilus shadow on the right side. The upper left chest showed increased bronchial markings approaching the periphery. The lower left costophrenic angle was denser than normal. The cardiac shadow obscured practically the whole lower left chest.

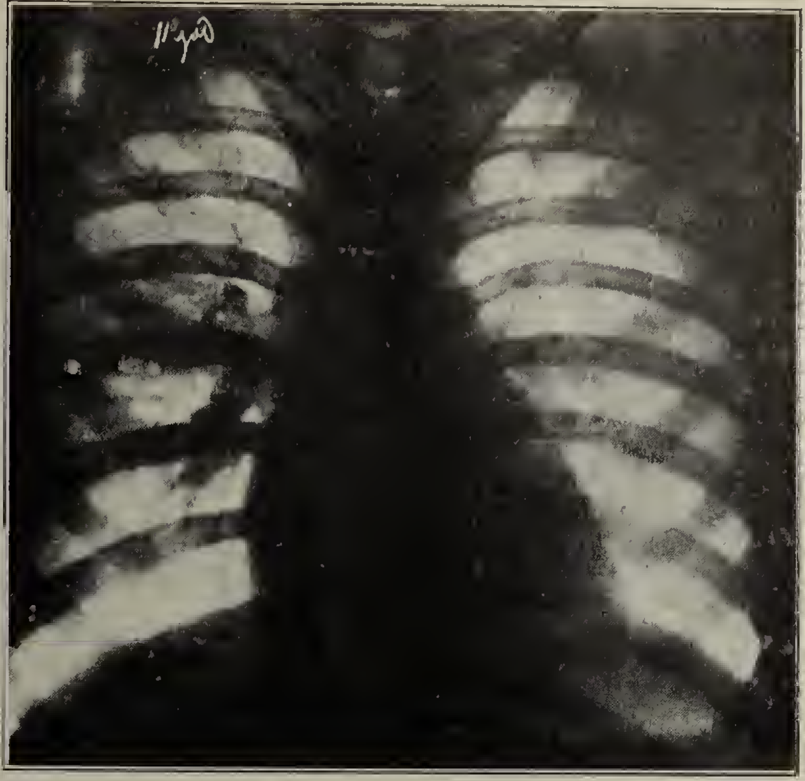

Fig. 11.—Normal heart in a child aged eleven years.

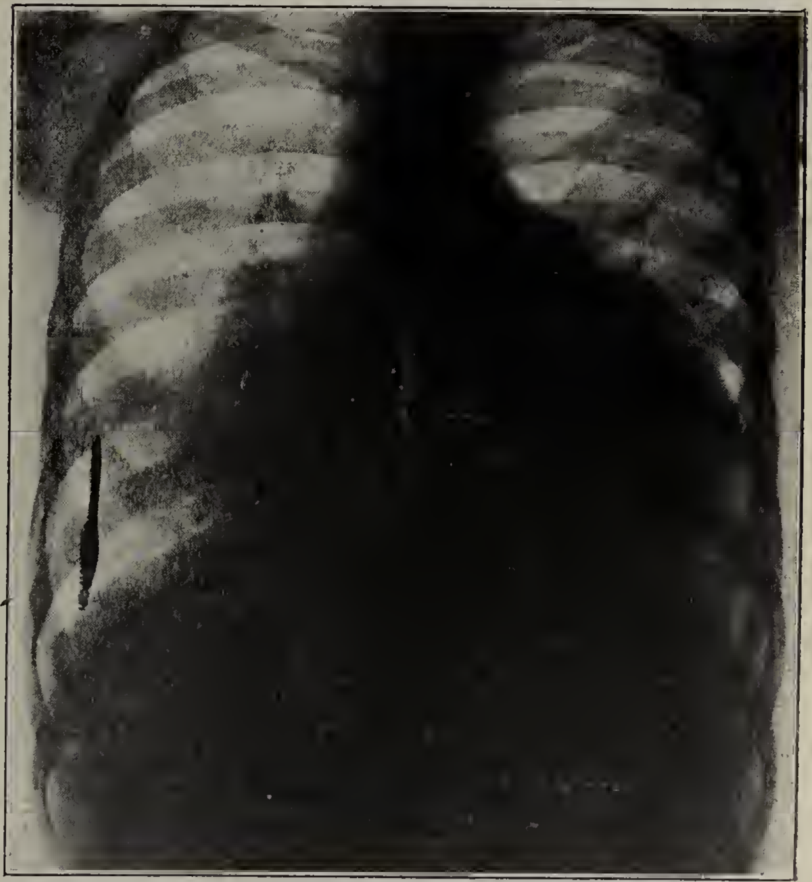

Fig. 12.—Large globular heart of mitral disease in a boy aged eleven years.

Figures 13, 14, and 15 illustrate mitral disease of the heart in patients of ten, eleven, and fourteen years of age, showing enormous enlargement of the left ventricle and enlargement of the right auricular region. Note the increased peribronchial thickenings and linear markings fan like in character confined to the upper lobe of the lungs.

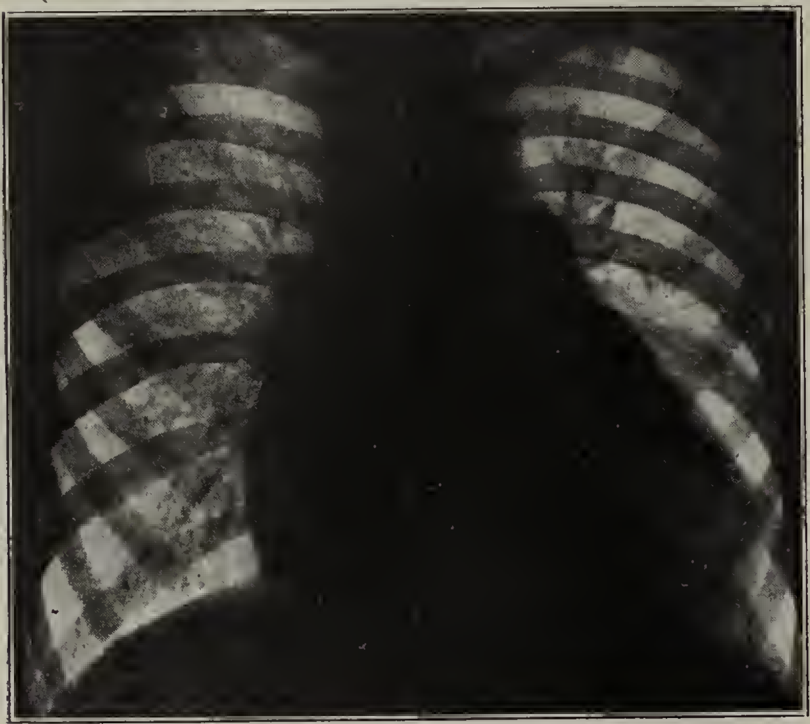

Fig. 13.—Large heart of mitral disease in a child aged ten years. Note increased bronchial markings in upper lobes.

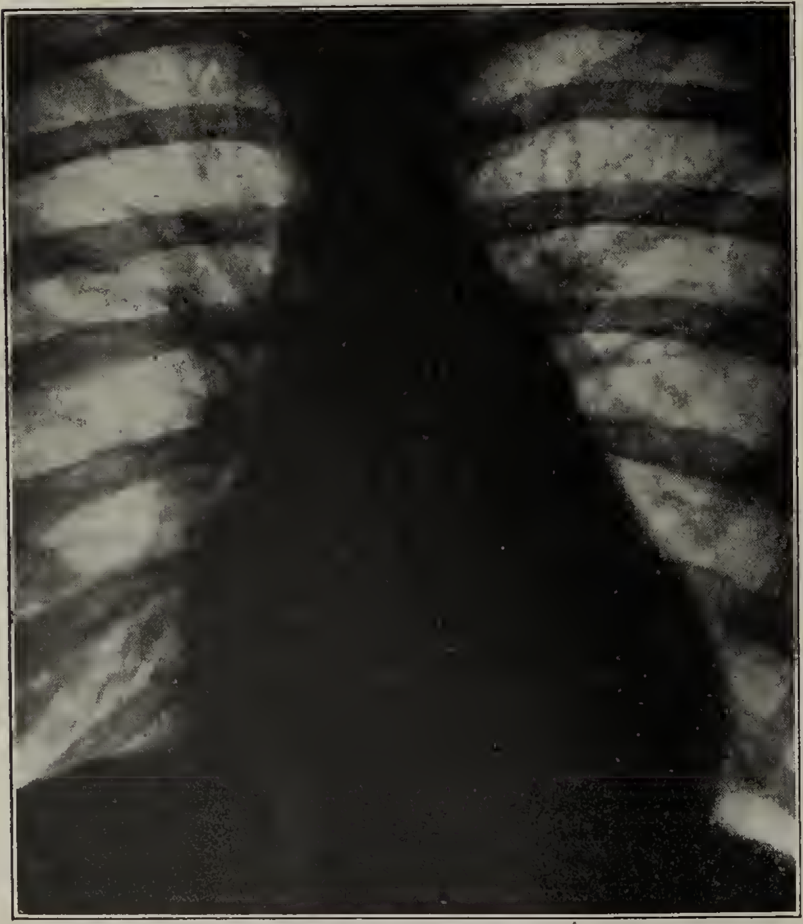

Fig. 14.—Mitral disease in a child aged eleven years. Note the dense bronchial trees fanlike in character confined to the upper lobes of the lung.

Aortic insufficiency and other valvular lesions occur with relative infrequency in young children. Kerley states that the ratio of aortic to mitral diseases is about one to fifteen. We are unable to show any x ray findings of these conditions. In diseases of the myocardium it is important to consider the physical signs in conjunction with the plate findings and the fluoroscopic examination, which definitely visualizes the activity of the heart. The radiograph will show a dilated heart with increase of the transverse diameter.

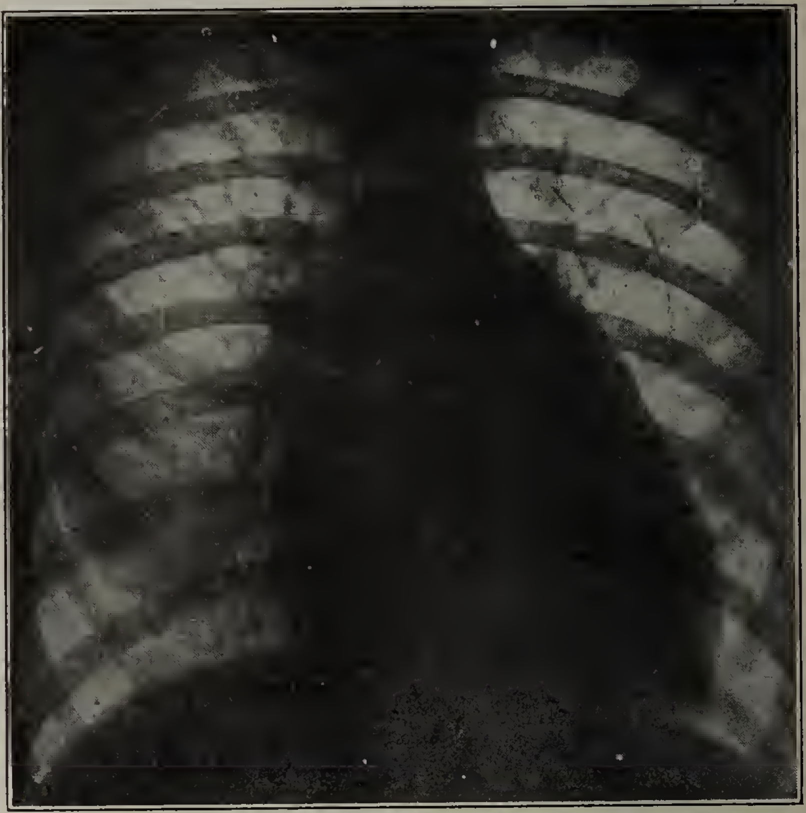

Fig. 15.—Enormous enlargement of the heart due to mitral disease in a child aged fourteen years.

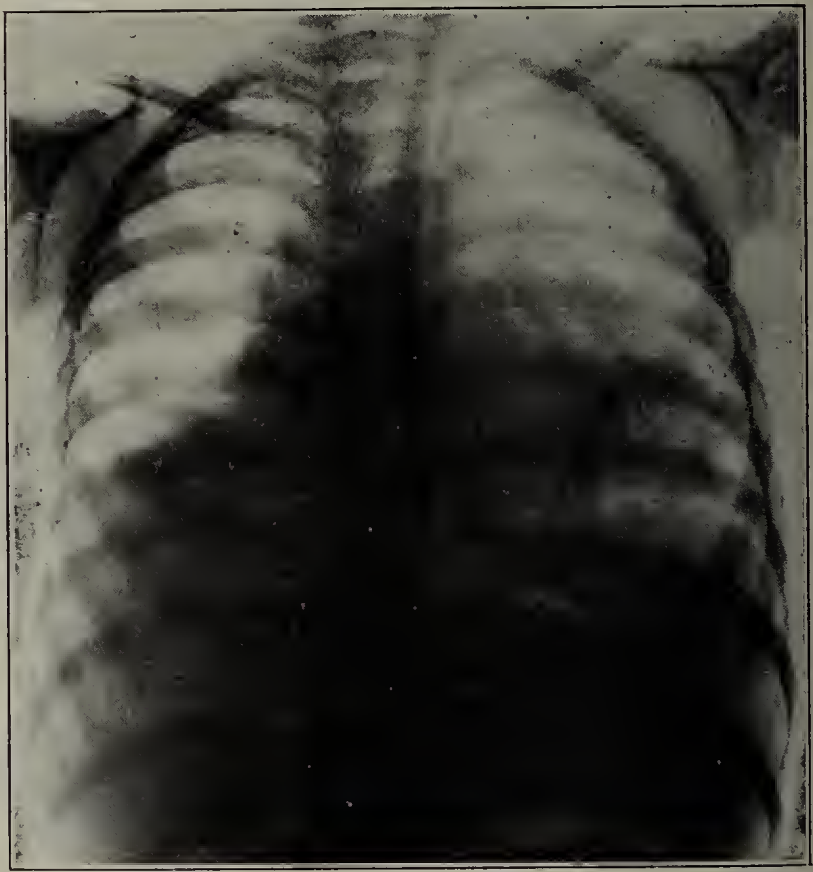

Fig. 16.—Showing symmetrical enlargement of the heart due to pericardial fluid, in a boy aged six and a half years.

Diseases of the pericardium are found in older children. Effusions are differentiated by changes which occur in the physical signs when the patient assumes a recumbent or sitting posture. This can be demonstrated by means of fluoroscopy or the plate examination, in the vertical and horizontal position. Normally there is slight change in the shadow of the heart due to postural changes but in this condition the shadow is more definitely observed.

The x ray findings are as follows: a, heart globular in shape, enlarged symmetrically; b, larger in the recumbent position; c, obliteration of the costocardiac angle; d, diminished visual impulse of the heart on fluoroscopic examination.

Figure 16 shows the röntgen examination in a case of a boy of six and a half years, suffering from disease of the mitral and aortic valves with pericardial and pleuritic effusion. The heart is globular and enlarged to the right and left, with obliteration of the costocardiac angle.

Figure 17 shows the change in the cardiac shadow after aspiration. The heart is diminished in size in its general contour throughout. The costocardiac angle shows the presence of pleuritic adhesions.

From the study of these cases the following conclusions have been drawn:

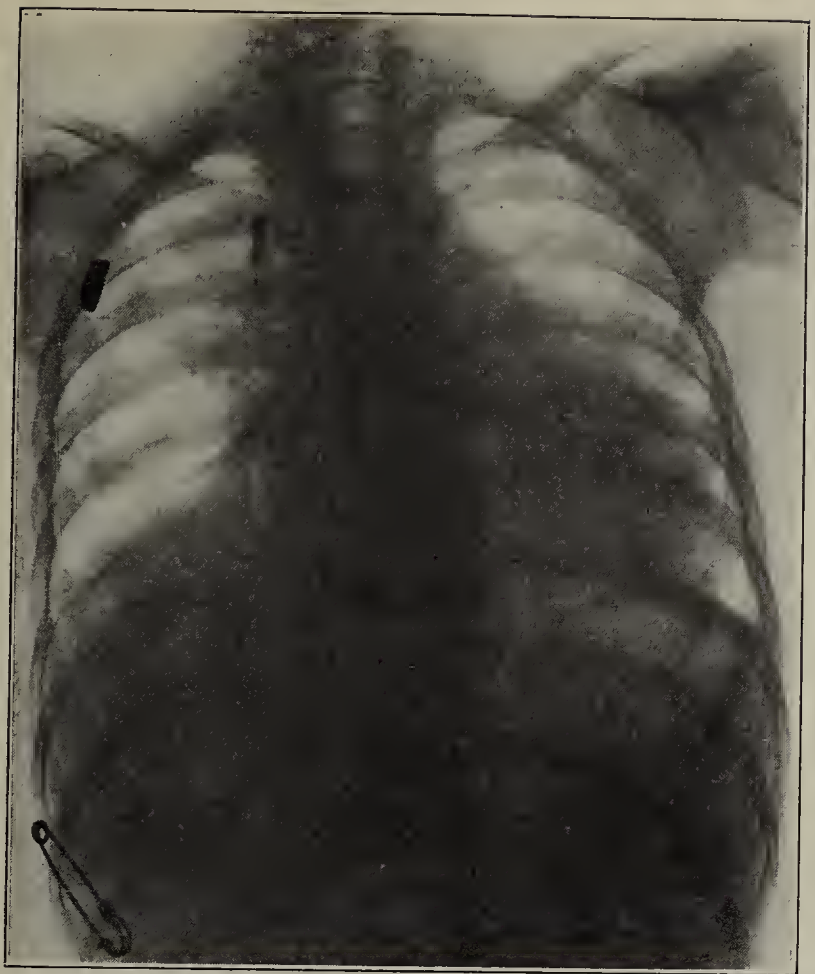

Fig. 17.—Röntgenograph after aspiration. Note diminished size of the cardiac area and adhesions in the costocardiac angle.

CONCLUSIONS.

1. The x ray examination in cardiac diseases of young children is of material aid in confirming physical signs.
2. It presents an accurate method of differentiating normal from abnormal hearts in children at different ages.
3. Progress of the disease may be noted by successive x ray examination.
4. At all ages in the normal, there is a constant ratio between the transverse diameter of the heart and the transverse diameter of the chest.
5. As a method of differentiating between congenital heart disease and thymus disease it is invaluable.
6. Associated pathological conditions of the chest can be demonstrated.
7. Advanced cardiac disease is associated with marked increased peribronchial shadows, fanlike in character, confined to the upper lobes of the lungs.
8. Distortions in the shadow of the heart due to imperfect technic may simulate pathological conditions.
9. Successive x ray examination should be taken in the same positions at some distance and with the same exposure.

Myocarditis in Children

By J. EPSTEIN, M.D.,

New York,

Attending in Pediatrics, Vanderbilt Clinic; Chief of Pediatric and Cardiac Clinics, Beth Israel Hospital.

The first thing that holds the physician's attention in the routine examination of the heart is that mysterious sound which is commonly called murmur. Since murmurs are largely the result of valvular deformities and endocarditis, the endocardium has received the greatest attention in cardiac diseases. The myocardium, which represents the main structure of the heart, and in which reside the principal functions of the heart, is frequently overlooked. Especially during childhood, when the heart is free from coronary sclerosis and other chronic degenerative changes, the myocardium has received very little of the physician's attention.

It is well to bear in mind that a murmurless heart is not necessarily a sound heart and a murmuring heart does not always mean a diseased heart; that murmurs are vibratory sounds produced in the wall of the heart or bloodvessel by the blood current when it deviates from its normal course, streams over a rough surface, or meets with some impediment. Murmurs may be caused by endocarditis, myocarditis, or myatonia cordis.

Murmurs may be classified as intracardiac and as extracardiac. The intracardiac murmurs may be divided into congenital and acquired. Congenital murmurs are the result of some structural error in the makeup of the heart. Acquired murmurs are due to disease or dysfunction of the heart. The extracardiac murmurs or friction sounds are pericardial, pneumopericardial or pleuropericardial.

For a clearer understanding of cardiac pathology, a murmur must not be looked upon as representing heart disease but as a symptom of heart disease. Valvulitis with its murmurs is the result of heart disease, just as paralysis is the result of brain disease. It is, therefore, erroneous to diagnose a case as mitral or aortic disease, mitral or aortic systolic or diastolic, as is so frequently done. The proper diagnosis should be endocarditis, or myocarditis or myatonia with mitral or aortic or pulmonic insufficiency or stenosis. Whether a murmur is systolic, diastolic, presystolic or prediastolic depends on the time of its occurrence in the cardiac cycle.

Since myocarditis does not produce as many thrilling murmurs as endocarditis, myocardial diseases with all their baneful consequences frequently remain undiagnosed and untreated. There are many more diseases which predispose to myocarditis than to endocarditis and myocardial affections are more frequent than endocardial. Many obscure disorders in circulation, respiration, and digestion can be traced to myocardial insufficiency.

During infancy and childhood, malnutrition, nutritional diseases, and metabolic disorders may cause considerable damage to the myocardium. The structural and functional integrity of the heart muscle depends mainly on an adequate and suitable diet. Any metabolic disorder which will interfere with the proper nutrition of the general musculature, will affect the heart muscle to a great extent, because of the greater nutritional requirement of the heart to keep up its incessant work. Diphtheria, scarlet fever, typhoid fever, influenza, whooping cough and rheumatic fever, are most damaging to the heart muscle. Anemia, thyrotoxin, congenital syphilis, tuberculosis, and endocarditis, as well as pericarditis, attack the structural and functional usefulness of the heart muscle. In fact, all specific, infectious and contagious diseases, and all chronic foci of infection, affect the cardiac musculature. In later life, arteriosclerosis, chronic metabolic diseases, and physical and mental overwork cause myocardial degeneration.

The effect on the myocardium may be inflammatory or degenerative, according as it is caused by bacteria or by toxins. The changes in the heart muscle may vary from simple to purulent myocarditis to various kinds of degeneration and fragmentation. Either the parenchyma or the interstitial tissue may be mainly affected.

Endocarditis, myocarditis, and myatonia cordis are the principal intracardiac disorders. In endocarditis the disease attacks the inner part of the heart and the valves are secondarily affected. In myocarditis the muscle tissue is diseased, while in myatonia cordis there is no cardiac lesion but a lack of cardiac tonus. Murmurs are usually present in all these cardiac disorders. Endocardial murmurs are loud, forcible and spreading. Myocardial murmurs are soft, weak, and limited. In atonia cordis or myatonia cordis there is a blowing systolic murmur in a heart of normal dimensions, and in a patient who does not complain of cardiac trouble. The murmur is usually found in the course of a routine physical examination.

One of the fundamental, physiological properties of muscle tissue and one of the principal functions of cardiac muscle is tonicity. A lack of muscle tonus causes a relaxation of the entire heart and a weakening of the valves. With each impact of blood during systole, the weakened valves vibrate and give rise to a systolic murmur. Such a condition may properly be called atonia cordis or myatonia cordis and the murmur may be called myatonic murmur. Febrile conditions, cardiac fatigue, anemia, malnutrition, improper cardiac innervation and hypoadrenia may produce a cardiac murmur either by causing a temporary myocardial hypotonia or by acting on a heart of poor muscular tonicity.

Myatonia cordis is probably the cause of that indefinite group of murmurs which are known as accidental, inorganic, hemic or functional. Since these terms are applied carelessly and interchangeably and without an exact anatomical or physiological basis, the term myatonic murmur, to take the place of the miscellaneous names, would be more appropriate. It would at once suggest an anatomical basis and a physiological dysfunction, for a murmur which probably has only one origin and many names.

The diagnosis of myocarditis in children is especially difficult, because of the diagnostic importance of the subjective symptoms in myocardial disorders, which a young child cannot intelligently express. Acute myocarditis in the course of some specific infectious disease may be diagnosed when there is an obscure sudden increase in temperature in a child that looks unusually pale, cyanotic, and distressed. He cannot bear the ordinary exertions and complains of precordial oppression. The heart is weak, slightly enlarged, and there may be a toneless systolic murmur at the apex. The extremities are cold and the pulse is empty, rapid and unsteady.

Subacute and chronic myocarditis can be diagnosed when there is a history of scarlet fever, typhoid fever, influenza or whooping cough in a child who complains of shortness of breath, heaviness, palpitation or pain in the cardiac region. He is disinclined to play and is easily tired on exertion. There may be digestive or respiratory disturbances and a trace of albumin in the urine. On examination, the child looks worn out, pale, or slightly cyanotic. The heart is usually enlarged, the sounds lack the normal muscular vigor, and there is a soft systolic murmur at the apex, and occasionally a reduplication of the second sound. The peripheral circulation is poor and the pulse is slow or irregular.

The treatment of myocarditis in children consists mainly in lessening or removing the general or focal infection, which injures the myocardium, and in prolonged rest. A great deal of physical and mental quiet should be enforced during and after all infectious diseases. The tired heart needs rest and judicious feeding for its recuperative power. During the acute stage of myocardial injury, codeine or morphine in small doses quiets the patient and conserves cardiac energy. In chronic cases, the underlying cause should be removed. Good food, fresh air and iron, arsenic, and strychnine will restore cardiac strength. Digitalis should be given when there is any evidence that the heart cannot do its work. Graded exercises are beneficial. Many obscure, chronic, circulatory, respiratory and intestinal diseases are cured by restoring a weakened myocardium to its normal strength.

Myocarditis in children is quite common and is just as commonly overlooked. A child with a history of diphtheria, pneumonia, scarlet fever, typhoid fever, influenza, or whooping cough is a potential myocardiac. Subjective symptoms of cardiac fatigue and objective signs of a slightly enlarged heart, a soft systolic murmur, of a quality peculiarly myocardial, and a pulse with some abnormality in rate, rhythm, volume or tension, makes the diagnosis. Proper timely care will save many a heart from an ultimate breakdown.

213 East Broadway.

Diagnostic Points in Diphtheria

By ARTHUR I. BLAU, M.D.,
New York.

The cases of diphtheria most commonly encountered are characterized by manifestations of varying description. This applies particularly to the pharyngeal and nasal forms of the disease.

A typical textbook pharyngeal diphtheria is relatively infrequent. Its signs and symptoms are sufficiently pathognomonic as a group to make a diagnosis easy. One can be reasonably certain of the correctness of diagnosis in a case of more or less sudden onset, in which there are sore throat, fever of 102° F., glandular enlargement at the angles of the jaw, general malaise, and a firm greyish white pseudomembranous exudate on the tonsils, and possibly also on the pillars, palate, or uvula. The cases ordinarily met, however, do not present so distinctive a picture, at least not at an early stage of the disease. Little or no constitutional symptoms are present in many cases, with but a slight elevation of temperature, and a small membranous patch on one or both tonsils, or on other parts of the pharynx; or the membrane may appear in small, firm, creamy white spots, which eventually coalesce.

Yet in most cases, if not all, these various anomalous though common forms, one or more of the signs and symptoms are sufficiently suggestive to put us on the right track, and then it is equally the characteristics and the presence of certain signs or symptoms which are suggestive in the diagnosis. The mere presence of a sore throat in a child is suspicious, especially so if its duration has been two or three days or more, and a culture should at once be taken. If in addition there is a slight elevation of temperature, say no higher than 101°, the suspicion becomes more suggestive. Not rarely the culture at this stage is found positive, though there is no exudate in the throat, and the further progress of the disease can be arrested by the prompt administration of antitoxin. If upon examination of the throat we discover a faint rim of a whitish film on one or both tonsils, or on the borders of the soft palate or uvula, we can be fairly certain that we are dealing with a diphtheritic membrane in its incipiency. A culture should no longer be delayed, for we can still arrest the full development of the disease by instituting the proper treatment. If the patient is not seen at this stage, or if the proper treatment has not been carried out, the further progress of the disease will make the diagnosis an easy matter.

Pharyngeal diphtheria is most often mistaken for follicular tonsillitis, and vice versa. Yet by carefully analyzing the signs and symptoms, we can avoid many pitfalls. A low fever, sore throat, and an exudate in the throat, are more suggestive of diphtheria than of tonsillitis. Diphtheria is characterized generally by a more quiescent onset, whereas tonsillitis by a more sudden onset, with high fever, i. e., 103° to 105°, and a greater degree of general malaise and prostration. The exudate in the former is usually in one continuous patch, or if in spots, they eventually coalesce. With the injection of antitoxin, intensification of the membrane is arrested within twelve hours. In tonsillitis the exudate is not really a membrane, but a cheesy mucous deposit, occurring in isolated spots in the tonsillar follicles, and can easily be removed without causing a surface bleeding. The white membranelike layer which covers the tonsils in some cases of tonsillitis, is not a membrane in reality, but a mucous mass easily removable. The early follicular exudation, unlike the early diphtheritic exudation, intensifies in its development for from twenty-four to thirty-six hours, in spite of treatment.

To summarize, the salient points in the diagnosis of pharyngeal diphtheria are the quiescence of the early constitutional manifestations (barring the more serious forms), and the nature of the exudate.

No definite membranous formation is usually present in nasal diphtheria, differing in this important respect from the pharyngeal type of the disease; nor are there generally any constitutional symptoms. This is the reason why nasal diphtheria is so commonly overlooked, and is often discovered accidentally or intentionally by bacteriological examination of the nasal discharge. In most instances, the only thing present is a persistent nasal discharge, occasionally blood tinged, and possibly also, but much less frequently, attacks of nasal bleeding.

The salient diagnostic point in nasal diphtheria is, therefore, a chronic nasal discharge, frequently bloody. Such discharges in infants and children should always arouse suspicion, and should be followed up with prompt cultural examination.

Laryngeal diphtheria is similar to the nasal form of the disease, in so far as its diagnosis does not depend upon the finding of a pseudomembrane. It is most often confused with spasmodic croup and catarrhal laryngitis or vice versa. It is important to bear in mind that at the onset the three conditions may be quite similar and therefore indistinguishable. However, it is not so much the onset as the progressive character of the membranous laryngitis, which differentiates it from other laryngeal forms.

Generally, the symptoms and signs at the onset of the membranous form are milder than in the other two. There is in all, hoarseness, croupy cough, stridor, dyspnea, and fever, of varying intensity. The fever in the membranous variety is usually low at onset, about 100° to 101°, a little higher in the catarrhal, and lower or absent in the spasmodic before the paroxysm. Of more importance in the early diagnosis is the general condition of the patient. In the catarrhal and spasmodic forms, the child is evidently not very sick and does not appear to be, and is inclined to continue at his play; in the diphtheritic form, on the other hand, there is early apathy, and the child appears to be sicker than the evident manifestations would warrant. Then again, while similar obstructive symptoms may be present in all forms of laryngitis, they differ in the manner of their occurrence, which is of distinct assistance in the diagnosis. In the membranous type the symptoms and signs are continuous, and, what's more, progressive, and after a duration of from eight to twelve hours all of them are greatly intensified. In the other forms the symptoms and signs are remittent and spasmodic, particularly in catarrhal croup, with a period of recession of symptoms of varying duration and degree. There are hoarseness and loss of voice in all, but the aphonia is usually only partial in the catarrhal forms, whereas it is complete in the membranous. Dyspnea and recession of the chest, with stridor, are also present in all, but in different degrees. In the membranous type these signs become extremely pronounced in a short time, with pallor of the lips and cyanotic finger tips. It is different in the laryngitis simplex varieties. The dyspnea, while quite marked during the paroxysm, is absent or slight in the interim, and the recession of the chest is only mild, even during the attacks.

The diagnostic points of membranous laryngitis are, therefore, early prostration and the progressive character of the disease.

It is to be borne in mind that the diagnosis of one of the types of diphtheria is facilitated by the presence of one or both of the other types of the disease. Again, a positive cultural examination will definitely prove the existence of diphtheria. Bacteriological findings are especially conclusive in the pharyngeal and nasal forms of the disease; in the laryngeal forms, on account of the impractibility or impossibility of reaching the seat of the disease, the findings are not conclusive if negative. Whenever there is the faintest suspicion of the existence of diphtheria, cultures should be taken, and it is even wise to do so in all inflammatory conditions of the throat occurring in children.

Spasmophilia*

By SAMUEL A. BLAUNER, M.D.,
New York,
Associate Pediatrist, Lebanon Hospital.

Spasmophilia is distinctly a disease of infancy and early childhood. Its manifestations take on varied forms, and frequently its symptoms are entirely latent, when its presence can be readily proved by Erb's electrical reaction. But whether latent or active its principal importance lies in the fact that convulsions, such a common disorder of childhood, are one of its principal and most common symptoms. Heretofore we were wont to look on convulsions in early childhood, whether idiopathic or occurring with the onset of acute febrile conditions, as of no great significance; in fact, the beginning convulsions in the acute febrile conditions were considered symptoms of the acute condition itself; but now, with our knowledge of spasmophilia, we know that in the majority of instances the convulsions are an expression of a tetanoid condition which has been made manifest or active by an intercurrent disease, and as such must be considered of importance as not infrequently they lead to a fatal termination.

Spasmophilia is really a hyperirritability of the peripheral motor nerves of the central nervous system and occurs in early childhood between the ages of three months and five years, rarely occurring beyond these limits. It is a disease of all strata of society attacking the well to do as well as the poor, the well nourished as well as the undernourished, although it is more common in infants surrounded by poor hygienic conditions, and on that account is frequently associated with rickets. Rickets, on the other hand, must not be confused with spasmophilia, for it is well established that they are entirely two different conditions, as it has been shown conclusively that not only are the blood chemistries entirely dissimilar but the pathology and symptomatology are entirely different. While not infrequently one encounters spasmophilic babies who are well fed, bright, happy and of good color and with no signs of rickets, on the other hand we find rhachitic babies who, if there were identical conditions, would show some of the pathognomonic signs of spasmophilia. As both these diseases are metabolic conditions dependent on the disproportion of the various mineral elements in the blood, they will of necessity be more or less concurrent, but it is well to remember that they possess entirely different pathology and symptomatology and for that matter require an entirely different therapeusis. In the presence of the serious symptoms of convulsions it would be a mistake to look upon spasmophilia as an expression of rickets and expose the child to the acute dangers of spasmophilia when its therapeusis is not only entirely curative but entirely different from that of rickets.

Spasmophilia, as has been said, is a hyperirritability of the peripheral motor nerves and as a result all the symptoms are motor in character. Spasmophilia, however, may be entirely latent, active symptoms being entirely absent, its presence being detected by the elicitation of the various pathognomonic symptoms, especially the Erb's electrical reaction. On the other hand, the symptoms may be active from the beginning, in which case it possesses not only its own symptom complex but also those of the latent form, or, which is not unusually the case, the active form is ushered in with generalized convulsions, either idiopathic or as the result of an acute febrile disease. The principal symptoms of the inactive type are the Chvostek symptom, the Trousseau symptom, and electrical hyperirritability.

In private practice, where access to an electrical machine is not possible, the diagnosis of latent spasmophilia will depend entirely on the Chvostek and Trousseau symptoms. Unfortunately these symptoms are not always present, and when present the Trousseau, which is the more pathognomonic of the two is not always constant, and as a result the majority of latent cases will be overlooked and the present spasmophilia recognized only when the active stage is ushered in by convulsions. Perhaps these convulsions for the moment are not serious and no great importance is attached to them, but it is well to remember that at some other time, especially when they occur at the onset of an intercurrent disease, they may be most severe and trying, terminating not infrequently in death. When we realize we are in the presence of an absolutely curable condition, which as a result of our oversight makes the intercurrent condition more difficult to handle, we will be impressed with the importance of examining every child under five years of age for latent Chvostek and Trousseau symptoms, and if possible the electrical reaction.

---

*Read before the Eastern Medical Society, May 1922.

The Chvostek symptom is not pathognomonic but is the more constant of the two, and consists of a contraction of the orbicularis palpebrum when the facial nerve is tapped just in front of the ear. The degree of contraction will depend upon the degree of the spasmophilia and in the more active cases a slight tapping of the facial nerve will throw many of the facial muscles into contraction. The Trousseau symptom, on the other hand, is an artificial tetany of the hand produced by pressure ischemia and is best obtained by pressing the bracial artery for a few moments just above the cubital fossa. The Trousseau symptom is not very constant but when present is especially pathognomonic of spasmophilia.

Of high diagnostic importance is the reaction of the peripheral motor nerves to the galvanic electrical current. The entire symptomatology of spasmophilia is dependent upon this irritability of the motor nerves and as a consequence the galvanic current will call forth a response different from the normal. Ordinarily with normal children the muscular contraction consequent upon peripheral nerve stimulation is more or less constant, that is, a contraction will begin to occur only when a certain milliamperage is obtained, but in spasmophilia it has been found that a much weaker current is necessary for a contraction to occur, due of course to the hyperirritability of the nervous system. Unlike the Chvostek and the Trousseau symptoms this symptom is constant and absolutely pathognomonic and is present in both active and latent cases. What makes this symptom still more important is the fact that this hypersensitiveness to reaction diminishes as the case improves and is gone with the cure of the condition.

Thiemich and Mann, of Germany, who have studied the question of electrical reaction in spasmophilia, with a view of obtaining a definite pathognomonic milliamperage figure in spasmophilia, found that of the various combinations that can be made, such as anodal closing contraction, cathodal closing contraction, anodal opening contraction, and cathodal opening contraction, for practical purposes cathodal opening contraction alone should be used for diagnostic purposes, and they therefore have formulated the rule that all cathodal opening contractions under five ma. are to be considered spasmophilic. Another interesting feature of the electrical reaction is the character of the response. In normal cases the electrical response is quick and sharp, while in spasmophilic cases it is slow and sluggish.

The active symptoms of spasmophilia are few and variable and depend entirely on the degree of activity of the conditions, the laryngismus stridulus being the most common, convulsions next in frequency, and general rigidity least common of all.

The stridulus is a distinct inspiratory crowing sound heard only in inspiration and is unaccompanied by any pathological change in the larynx. This crowing sound may be short or long, and in severer cases may be present with every inspiration or may be called forth only by deep inspiration or crying or when the child is in a temper. The expiratory phase of respiration is entirely normal and is of importance because of the aid in the differential diagnosis of other laryngeal conditions. There is also a congenital stridulus, not very infrequent, which stimulates spasmophilic stridulus very closely, but its onset at birth helps in the differentiation. Besides this congenital condition there are instances of congenital lues which give you a stridulus, but the early onset and other general symptoms will help in the diagnosis.

The importance of spasmophilia lies in the fact that convulsions are a prominent symptom and from observations and studies it is not amiss to say that the majority of idiopathic convulsions in children under five years of age are spasmophilic in character. Furthermore, it is also safe to say that in many instances the convulsions which usher in an acute febrile condition are spasmophilic in character. When it will be realized that spasmophilic convulsions can become very severe, especially with the onset of an acute infectious disease, and at times become fatal, and furthermore that these convulsions are the first warning of a previous latent spasmophilia which was easily amenable to treatment, we will understand the importance of looking for early or latent symptoms of spasmophilia in childhood.

The tetany or tetanoid contractions are late symptoms, and before spasmophilia became a recognized condition a rather common symptom, but now with early recognition and treatment is very rarely seen except in debilitated infants. Occasionally the tetanoid contraction involves the entire musculature, especially the muscles of the neck and back, giving rise to a marked opisthotonus and simulating very closely a basilar meningitis.

The diagnosis of spasmophilia is as a rule very simple if only the possibility of this condition is kept in mind. In active cases recognition is very easy, for in no other condition is a Trousseau, Chvostek and stridulus so pathognomonic, particularly in the presence of a previous history of idiopathic convulsions. Where there is access to the galvanic current the cathodal opening contraction surely will dispel any doubt. Where, however, the disease has been latent and the active condition is ushered in by convulsions either with or without elevation of temperature, diagnosis may be somewhat more difficult and if the Chvostek and Trousseau reactions are absent, the cathodal opening contraction alone will be of positive service. Sometimes in late neglected cases where the spasmophilia assumes the form of a general tetany, with marked opisthotonus suggesting a cerebral condition; or in early infancy before the third month in the socalled hypertonic infant where there is a general rigidity with a certain degree of opisthotonus, the diagnosis of spasmophilia may be somewhat difficult but the general history, age, the absence of the cardinal symptoms and especially the absence of the quantitative cathodal opening contraction, electrical reaction will readily differentiate the conditions.

Various have been the causes given for spasmophilia. Clinically the fact is well known that the majority of the patients are bottle fed and investigators have found that the elimination of cow's milk quickly relieves the condition. They found, too, that the calcium salts are decreased in the system and very recently Marriot and Howland have shown that the characteristic blood found in all cases of spasmophilia showed a marked reduction in the calcium salts and as the condition improved or was cured the calcium salts tended to return to normal. There can be no doubt that this deficiency of the calcium salts is the cause of the hyperirritability of the central nervous system, but even this must be secondary to some as yet unknown primary factor, for there surely must be a sufficient calcium salt intake in bottlefed babies.

The treatment, therefore, becomes a simple matter, by either putting the child on a diet free from cow's milk or giving some form of calcium, or for that matter both. In general, it is better to give the cow's milk free diet for it is more efficacious and more prompt, where the age of the child permits of such a change. In either case positive results will be obtained, but treatment must be continued long enough until all symptoms have disappeared, particularly the quantitive cathodal opening contraction, for otherwise recurrence will follow, and recurrence is not uncommon in spasmophilia.

Theory and Practice of Artificial Infant Feeding*

By S. HORWITT, M.D.,
New York,
Attending Physician, Vanderbilt Clinic, Department of Pediatrics; Assistant Physician, Mt. Sinai Dispensary, Department of Pediatrics.

We are all familiar with the dangers that menace the career of the artificially fed infant. Rickets, scurvy, tetany, gastrointestinal disorders, acute intoxications, anemia, marasmus, nutritional edema, reduced immunity and resistance in the face of infections—such are the morbid states which affect the bottlefed infant. Nevertheless, if artificial feeding is an evil, it is a necessary one, and it is our task next to discouraging it where possible, to render it safe for infancy where unavoidable. It is clear that the principles governing our efforts in this direction must be based on our conception of the factors that render artificial feeding in general and cow's milk in particular so hazardous for the human infant. I shall try, therefore, to pass in brief review some of the important doctrines that held sway over medical opinion on this subject ever since it began to be studied scientifically, commenting on them as I proceed.

After the chemical composition of both cow's and human milk had been learned and the differences noted, the remedy was sought in the correction of these differences (1). By diluting cow's milk and adding sugar and cream, mixtures can be obtained which, as regards the percentage of fat, protein, and carbohydrate, approximate human milk. Such devices were rather optimistically styled "humanization." However, a dilution of cow's milk sufficient to reduce the aggregate of its protein to the human level still leaves its casein more than twice as high as it occurs in woman's milk, while dilutions high enough to make the casein equal in quantity to that of human milk are inadequate for infant feeding. It must be borne in mind that casein—or curd—indigestion was long regarded as the greatest difficulty of bottle feeding. To overcome this difficulty expedients were devised to prevent the formation of tough, massive, casein curds in the infant's stomach, such as the addition of lime water, cereal gruels, sodium citrate, and peptonization (2).

Some observers were inclined to incriminate the fat of cow's milk as the source of trouble. Its volatile fatty acids were said to irritate the infant's stomach. As a remedy it was proposed to skim the milk and for its cream substitute lard, cocoa butter, or olive oil.

In the light of our present knowledge we may say that an attempt to imitate human milk is an impossible task. The fat is qualitatively different, the salts are quantitatively different, and the protein is different in quantity as well as in quality. The percentage of casein is higher in cow's milk, and the casein coagulates differently. The precipitin test shows that the casein is biologically different from that of woman's milk (3). There are other biological differences, such as ferments and immune bodies which are specific in each milk for its species, and therefore useless for the alien species. We know, furthermore, that the nutritive value of proteins cannot be rated in terms of percentages. We now know that the nutritional value of proteins is determined by the kind and quantity of aminoacids in its molecule, and casein, containing less of these essential aminoacids than lactalbumin, must be consumed in larger amounts to insure proper growth (4). Here we have a biological explanation for the empirically observed fact that infants cannot be kept long on a formula in which the percentage of protein equals that of mother's milk. As to the use of such devices as sodium citrate or peptonization, it may be said that we are coming more and more to look with disfavor upon denaturing procedures, which are likely to impair the nutritional value of such a good food as cow's milk. These methods are likely to damage the antiscorbutic properties of the milk. The same may be said of the attempt to substitute lard, cocoa butter, or olive oil for cow's fat, as alluded to above. Nutritional experiments have shown that these are the worst possible fats to give a growing animal, as they are utterly devoid of vitamine A (5).

---

*Read before the Bronx County Medical Society, December 20, 1922.

After the chemists came the bacteriologists. In the enthusiasm following the discoveries of Pasteur, all troubles arising from artificial feeding were laid to infection (6). Milk is such a good culture medium and the chances for infection so numerous! The watchword then was: Sterilization! Budin declared that milk, provided it was boiled, could be fed unmodified. It soon became manifest, however, that while boiling could be depended upon to prevent the transmission of typhoid, tuberculosis, and dysentery, as well as certain other diseases definitely of infectious origin and which, by the way, are comparatively rare, it was no panacea for dyspeptic states, nutritional disorders, and the common diarrheas, such as are encountered in artificially fed infants. Asepticism therefore did not solve the problem.

The most promising method of ascertaining the cause of the disturbances accompanying artificial feeding would seem to be the study of the syndrome which is typical of cow's milk feeding and known on the Continent as cow's milk dyspepsia (*la dyspepsie du lait de vache*—Marfan) or milk injury (*milchnährschaden*—Czerny). This syndrome is characterized by arrested weight, emaciation, distressed countenance, constipation, pale grey, puttylike stools of alkaline reaction, which contain an abnormally high amount of calcium and other soaps—the socalled soap stools. There may be periods of diarrhea, when pale, fetid stools are evacuated. The urine contains an abnormal amount of ammonia. There seems to be an improper utilization of fat and an abnormal loss of alkalies (7). So much is clinical fact, as to which there is universal agreement. When, however, it comes to its interpretation, there is great diversity of opinion. Casein putrefaction with autointoxication; fat intolerance, demineralization of the body with consequent acidosis; failure of the biliary and pancreatic ferments; faulty correlation of the quantity of sugar to that of protein and fat which hinders physiological fermentation—such are some of the meanings read into this x of *milchnährschaden* (8).

On one point, however, there is agreement among all observers, namely, that the only corrective for the "soap stool" and the cure and prevention of the associated malnutrition, is an adequate allowance of carbohydrates. To this all important fact we shall have occasion to return later.

Next to the misconceptions concerning the infant's food are those relating to the infant. It is not within the scope of this paper to discuss the place of constitutional inferiority and the rôle of peculiar diatheses in infant feeding. Possibly some form of vomiting, diarrhea or dyspepsia may be a manifestation of a neuropathic diathesis. Nevertheless, when one remembers the number of vomiting, dyspeptic, fretful infants who become placid, contented, soundly sleeping babes as soon as their nutrition has been improved, one is inclined to think that the rôle of diathesis in the general run of infant feeding must be limited. A further error is the conception firmly rooted in the minds of some of the profession that infant feeding is essentially a problem of infantile digestion. The tendency is to lay failures to dyspepsia, gastroenteritis, fermentation, putrefaction, failure of digestive ferments, as though these were primary entities. As a matter of fact, the infant is provided with all the digestive ferments found in the adults (10). Fermentative and putrefactive processes, as well as their associated flora, are secondary to and contingent upon the mode of feeding (11). As to the term gastroenteritis it should be noted that postmortem examination of the digestive tract of infants suffering from malnutrition, dyspepsias and even severe, toxic diarrheas—barring of course the dysenteries—are negligible. Obviously, therefore, we must look for the explanation of the accidents of artificial feeding beyond the intestinal mucosa. The method of approach must be metabolic and nutritional, as well as digestive.

At this point it is pertinent to inquire under what circumstances, if at all, the "artificially fed" adult may suffer from disturbances analogous to those occurring in infancy as they were detailed at the outset of this paper. In normal times adults are strikingly free from them. In communities, however, subjected to siege, blockade, famine, camp and prison life, there appear individuals suffering from cachexia (marasmus), scurvy, rachitic bone lesions, nutritional edema (war edema), tetany, reduced immunity and resistance in the face of infection—in fine, the whole gamut of diseases which we are in the habit of associating with artificially fed infants. European medical literature since the armistice abounds in highly interesting, if painful, accounts of the nutritional experiments conducted under the auspices of Mars in a laboratory as vast as a large part of the Eastern hemisphere and with countless human beings instead of guineapigs. Beriberi among British soldiers in Mesopotamia as a result of using highly milled flour, scurvy among the Indian soldiers who would not eat fresh horseflesh (12), xerophthalmia among Danish children as a result of fat privation (13), cachexia and edema among the people of the Central Empire as a result of low caloric allowance and of fat and protein shortage (14, 15), late rickets in youths and osteomalacia in adults, as well as tetany as a consequence of inanition plus the debilitating effect of influenza in 1918-1919 (16, 17, 18). Here is a wealth of nutritional experiments upon humans with vitamine deficiencies, general inanition, fat and protein inanition, and inanition plus the debilitating factor of infectious disease.

These facts, it seems to me, should prove illuminating in our endeavor to unravel the essential fault of artificial infant feeding. Czerny and Keller's syndrome of *mehlnährschaden,* flour injury resulting from a onesided carbohydrate alimentation, was closely mimicked by war edema (14). As to the syndrome of milk injury, one could hardly expect its reproduction during the war as it presupposes a ration, sufficient in fat and protein and poor in carbohydrate, whereas in the event of blockade, protein and fatty foods give out long before the carbohydrate foods. Considering, however, its mode of origin, we find that it is most likely to occur when no sugar, or an insufficient amount, is given along with cow's milk. Marfan, who at one time was induced by the teaching of Budin to feed the infants under his care on unmodified milk, found that in the great majority of those under six months the syndrome of milk dyspepsia developed (19). Furthermore, as was pointed out above, the only corrective for this nutritional disturbance, as well as its prevention, is a proper carbohydrate allowance. From these considerations we may conclude with Finkelstein that the socalled milk injury syndrome is a product of carbohydrate inanition (20).

Viewed in this light, infant feeding becomes preeminently a problem of correct rationing of an individual who, like an inmate of a prison camp, is dependent upon the mercy, wisdom, or folly of others for the choice of his fare. The chances of error are greater in the case of the infant, because those in charge lack the helpful suggestions which instinct and appetite would give in planning a diet for an adult. The possibilities for harm, too, are so much greater in the case of the infant, for the reason that to the requirements of maintenance, which are much higher to the unit of weight than in the adult, there is superadded the imperative element of growth. The infant doubles his weight in six months, and trebles it in the first year. It can therefore be readily understood why nutritional diseases, which in the adult take years for their development, are in the infant precipitated in so many months or even weeks (27).

Now, mother's milk having been designed for the same species constitutes a well balanced ration in every way. It has an optimum of fats, proteins and carbohydrates, salts, vitamines, perhaps also hormones and immune bodies, so that the most primitive mother, provided her supply is ample and she is healthy, will succeed regardless of the technic she uses or abuses. If I may use a vulgarism, it is fool proof. Once the infant is taken off the breast, his nutritional fate lies between the Scylla of excessive, improper and contaminated food and the Charybdis of an insufficient, inadequate, devitalized or onesided diet. The first danger received ample attention in the past. In fact it was overemphasized, whereas the dangers of inanition received only scant passing notice. The tendency was to implicate this or that food element, instead of looking in the direction of a possible deficiency of one or of the other food requirement. Yet a critical survey of the histories of marantic infants seen in hospitals or dispensaries will disclose that, barring infectious diseases or organic defects, inanition general or specific, plays the largest etiological rôle.

EXAMPLES.

1. Infant, one month. For past two weeks fed on malted milk, one dram, water two and a half ounces, q. three hours. Extreme emaciation. Example of general inanition.

2. Infant, two and a half months, milk and water āā three ounces, q. three hours. "Vomits cheese. Emaciated. Sugar inanition. Also, because of excessive quantity, vomiting, and therefore general inanition.

3. Infant, five months. Milk and water āā four ounces, granulated sugar ʒi, q. three hours. "Soapstool." One pound underweight. Initial stage of "milk injury."

4. Infant, four months. Nursing unsuccessful and doctor advised barley water. Thereafter baby refused breast and was kept for three weeks on barley water. On admission weighed ten pounds, anemia, emaciation, skin feels tense, in parts glossy and scleremic. Here is an instance of *mehlnährschaden* of Czerny, a counterpart of war edema, due to general inanition with the particular deprivation of fat and protein.

5. Infant, six months. For three months on milk and water āā four ounces. Loss of weight. Emaciation. Carbohydrate starvation.

6. Infant, six months. On dried milk for two months. Gained at first. Recently, diarrhea, arrest of weight despite sufficiently high calories. Diagnosis—sugar insufficiency. When changed to whole milk formula plus a proper quantity of sugar, his weight and vitality made wonderful progress.

Naturally, not all feeding histories are clearcut. A number of deleterious forces may have been at work in a given case, simultaneously, and it may be impossible to determine the nature of the nutritional injury. Dyspepsia from overfeeding or improper food, deficiency of an important food element, avitaminoses, and infections may be combined in various degrees and superimposed in various combinations. The end result may be in one case rickets, in another von Jaksch's anemia, in a third an obscure form of marasmus, in a fourth celiac disease. We well know how difficult it is to explain these syndromes on the basis of a single and specific etiological cause. In fact, in the famine diseases mentioned above several factors were contributory. Starvation, partial inanition, hard work, cold, infectious diseases, avitaminoses. This broad, nutritional viewpoint will save us from therapeutic narrowness.

As a concluding remark it may be said that while chemistry, bacteriology and metabolic studies have contributed immensely to our knowledge of infant feeding, many of its problems can for the present be solved only by the direct nutritional method of investigation.

To summarize, then, the considerations upon which we are to base our principles and practice of infant feeding are as follows: Imitation of human milk is an impossible task, and should therefore not be a determining factor. Imitation is only possible in the case of sugar, and even here the superiority of lactose over other sugars has not been demonstrated. Curd indigestion is largely a misconception, and its correction is rarely called for. At our clinic we almost never see occasion to treat it or even to take it into account. We have long since proscribed lime water, sodium citrate, peptonization. The use of sterilized or aseptic milk will not expiate the sins of an improper formula. The fear and trepidation with which the use of plain cow's milk is approached by the uninitiated is unfounded. Probably a good many of the failures attributed to cow's milk as a whole or to any of its particular constituents were in reality due to lack of knowledge and appreciation of the nutritional needs of the growing infant. By the same token one must guard against misinterpreting such symptoms as loss of weight, restlessness, vomiting, diarrhea. They do not invariably imply overfeeding, food intolerance, curd indigestion, nor do they spell higher dilution, predigestion, reducing this or that food constituent. One should palliate these symptoms while treating the underlying nutritional fault. In fact, we have seen vomiting and diarrhea clear up under an adequate formula.

As to the attributes of an adequate formula: 1. It must contain sufficient calories. 2. The calories must be properly apportioned between fat, carbohydrates, and proteins. 3. The food allowance must not be excessive. 4. The volumetric quantity must be right—neither too small nor too great. 5. It must not be destitute of growth promoting principles, or vitamines, either through denaturing processes, substitution, or onesidedness.

1. *Calories.*—The name caloric feeding is objectionable, inasmuch as it lays too much emphasis on the caloric aspect of the food as though its composition were a matter of indifference. The specific value of food constituents, quite apart from their caloric value, and in fact even in the absence of any caloric import, as in the case of vitamines, has been discussed above. In the case of fat, however, we may assert that while it may have a definite rôle in nutrition and metabolism, even apart from being a purveyor of vitamine A (21), its quantitative requirement seems to be elastic, and within certain limits it may be replaced by sugar. The use of whole milk mixtures has stood the test of time, and it must be realized that in these mixtures the fat percentage is necessarily lower than in woman's milk. In fact, the use of whole milk mixtures was originally justified on the theory of isodynamy or caloric equivalence of foods (22). We may also point to the use of skimmed milk or buttermilk mixtures with apparent good results as examples of low fat feeding.

With these reservations in mind we will find the caloric appraisal of food one of the helpful criteria of a good formula. The figure usually given is forty-five calories to the pound for the first nine months, forty for the balance of the first year; overweight, quiet babies will do well on less, and puny, undernourished ones will require fifty to sixty or more.

2. *Fats, proteins, and carbohydrates.*—While it is still convenient to compute the quantities of these in terms of percentages, it is obvious that what really matters is the absolute quantity of each food principle. Accordingly, the protein requirement is said to be covered by the use of an amount of milk equal to one tenth of the infant's body weight, or one ounce and a half to the pound. The sugar need is given as one one hundredth of the body weight (22) or about one and a quarter dram to the pound. The fat requirement is generally met alongside of the protein allowance. Low fat and high sugar combinations are compatible with good growth and development. In fact, skimmed milk and high sugar combinations have proved very useful in our hands during the period of reparation in cases of denutrition (22). Possibly sugar is more readily utilized by the debilitated infant than is fat. Also the high protein may be of advantage because in the reparative stage of inanition protein retention is higher than normal (28). Nevertheless, to avert possible harm from a prolonged fat poor regimen, we skim less and less as the baby improves, until whole milk is reached. Exceptionally, top milk mixtures will apparently save the day, and we may surmise, although this cannot be definitely affirmed, that in these instances there is a higher nutritional need of fat than ordinarily.

3. *Hyperalimentation.*—This leads to dyspepsia. For a time the infant may do uncommonly well, its weekly gain may reach three quarters to one pound. Sooner or later anorexia, vomiting and diarrhea supervene. If long persisted in, it eventuates in denutrition and occasionally in the symptom complex of acute intoxication (cholera infantum).

4. The volumetric quantity of the formula, which is after all a question of covering the water needs of the body, may be given roughly as follows:

Three ounces to the pound during the first four months.
Two and one half ounces to the pound during the second four months.
Two ounces to the pound during the third four months.

It is rarely necessary to go much above forty ounces a day. When the volume of the food is excessive, part of it may be vomited or refused, partial inanition resulting in either case.

5. As to vitamines and the socalled growth promoting factors, orange juice should be given routinely as a convenient vehicle of both C and B factors (24). Vitamine A is supplied in the fat of the milk. After the eighth month small quantities of finely mashed vegetables, and, when indicated, also yolk of egg, which, in addition to vitamine A, also contains iron. The objection to these foods at this early age proceeded from the traditional distrust of the infant's digestive apparatus.

Undernourished infants require more food than normal ones of the same weight. For these the figures lie somewhere between those called for by their actual weight and the weight that would be considered normal. Actually, the optimum amount is arrived at by allowing less at first and then increasing until the gain is satisfactory.

A careful history and physical examination are the *sine qua non* of intelligent infant feeding. The presence of syphilis, tuberculosis, cerebral defect, cretinism, congenital heart disease, pyloric stenosis, or an acute infectious disease like grippe, pyelitis, otitis media, for example, will impede the infant's growth even when the feeding is ideally planned. Where there is no fundamental disease, one analyzes minutely and critically the feeding history in the light of the criteria detailed above. One aims to make a correct digestive as well as nutritional diagnosis and to correct or overcorrect the apparent fault of the preceding formula. One must be careful in the interpretation of such symptoms as restlessness, crying, vomiting, diarrhea, for they may be occasioned by either excessive or insufficient alimentation. Or, their cause may be parenteral, as, for example, grippe, otitis media. Having made up one's mind as to the formula indicated, one gives at first somewhat less than full strength. In fact, where the history indicates superalimentation, with poor appetite, the infant leaving part of each feeding, a temporary régimé of underfeeding, both caloric and quantitative with lengthened spacings, is indicated, to cure the gastric atony. But even where the trouble seems to be one of subalimentation, the first formula must be in the nature of an experiment. Nevertheless, one must have the courage of his convictions, and proceed boldly enough to get results.

ILLUSTRATIONS.

A. Infant, twelve pounds, three months:

Total quantity, 12x3 oz.=36 oz.
Milk, 12x1½ oz.=18 oz.
Sugar, 12x1 dr.=1½ oz. (or 12x1¼ dr.=2 oz.)
Water, 36—18=18 oz.
Calories per lb. (18x20)+(1½x120)=540; 540÷12=45 (or 50).
Directions: 5 oz. q 3 hrs. 7 feedings in 24 hrs.

B. Infant on breast until present. Imperative reason for weaning: serious illness or death of mother. First formula should be about two thirds of A:

Milk	12 ounces
Sugar	1 ounce
Water	24 ounces
Total	36 ounces

Calories, 30 per lb.

Directions: 4 to 5 oz. q. 3 hrs. Increase gradually until formula A is reached.

C. Previous formula excessive—calories much too high, quantity too large, perhaps high fat. Recently stopped gaining, takes only two or three ounces of the six to eight ounces offered. Some belching and regurgitation.

Directions: Water diet for the rest of the day. Next day give formula B, giving rather four than five ounces every three or, better still, every four hours, to cure dyspepsia, until appetite has improved. Then increase until formula A is reached.

D. Child is five months old, two or three pounds underweight. History of (a) injudicious feeding: quantity too large, seven or eight ounces at a time, fed whenever it cried, perhaps every two hours. Occasionally "gets a crust of bread," etc. Proceed as in C. When symptoms ameliorate, the quantities given in formula A should be exceeded, as underweight children must have greater food allowance than normal ones of same weight.

(b) Subalimentation. Appetite good. Quantity too low or sugar too low. Begin with formula A and rapidly advance, bearing in mind the quantities this infant's age would entitle him to. It is in cases grouped under D that the use of skimmed-milk-high sugar often yields gratifying results. The first formula for cases given in (b) may be like this:

Skimmed milk (1% Fat) 24 oz. 24x12.5=300
Water, 12 oz.
Sugar, 2 oz. 2x120=240
Total, 36 oz.
Calories, Total (1 oz. 1% Milk=12.5 cal.) 540
Calories per lb. 540 12=45
Directions: 6 oz. q 3 hrs., 6 feedings.

If all is well at next visit, increase the amount of milk or of sugar or both. The use of two sugars, as saccharose and dextrimaltose, for example, works well. Later on use two per cent., three per cent., four per cent. milk.

E. Baby still on breast but gain is arrested or precarious. Use complementary feedings. First formula is something like this:

Milk	7 ounces
Water	14 ounces
Granulated sugar	1 ounce
Total	21 ounces

Directions: Feed 2-3 oz. after each breast nursing.

F. Baby fifteen months old. Weighs seventeen pounds. Somewhat anemic. Perhaps stigmata of rachitis. History: Feedings irregular. Eats everything at the table in addition to one to one and a half quarts of milk. History of colds, coughs, rhinitis, etc. Recently anorexia. Daily calories above one thousand. Or, in some cases, takes one to one and a half quarts of milk and cares for little else. Here a radical reform in diet must be insisted. In the first instance underfeeding must be practised for a short period, milk reduced to twenty-four ounces, cereal one to two tablespoonfuls twice a day, one to two pieces of toast, orange juice. Calories reduced to six hundred or seven hundred. Number of meals reduced to four or five. Subsequently vegetables were introduced, apple sauce, prune juice, egg, perhaps codliver oil and iron. In the second instance one aimed at the same dietary as above. Firm dietary discipline as well as patient perseverance and training is necessary to reform the infant's morbid idiosyncrasies.

The above outlines are meant to be suggestive, and no rigid dogmatism is intended. The treatment of infants considerably underweight with severe nutritional disturbance, of acute gastrointestinal attacks with fever and perhaps intoxication is not within the purview of this paper. Cases of anaphylactic intolerance for cow's milk or for eggs are not considered.

Needless to say, figures in connection with infant feeding represent only averages, from which departures may be and often are indicated in individual cases. In fact, the ability to individualize is the distinguishing mark of the consummate infant feeder. The memorization of a few rules will not make an accomplished feeder, any more than it will make a finished radiologist or surgeon. Difficult, long neglected cases will tax the ingenuity of even the expert, while the treatment of advanced marasmus or decomposition (Finkelstein) is always trying and frequently disappointing. In these cases a stage has been reached where there is no mere arrest of growth to be resumed with improved opportunity. Here the cellular structure has suffered irreparable injury or decomposition. The withered organism has lost its capacity for reparation, even woman's milk avails nothing. It may be hoped, however, that with the application of the principles and rules laid down above, the occurrence of nutritional disasters will be averted. The further significance of rules and figures is their implication. If the nutritional requirements will be borne in mind and attended to, patent foods and stereotyped formulas will be found unnecessary and the claims made for them hollow. I believe that the skillful use of cow's milk has enough possibilities to meet almost every feeding emergency of the infant, that the less it is tampered with the higher its nutritional value. I consider the invention of new foods as ingenuity applied in the wrong direction. I think that the profusion of foods leads to the confusion of the feeder. I can only explain the vogue of newfangled infant foods by a human failing which was so well expressed by James Lind in 1755 in his treatise on scurvy (25). He says: "Some persons . . . would have more faith in some elaborate composition, dignified with the pompous title of Antiscrobutic Golden Elixir, or the like, than in the use of fruits and vegetables."

Infant Feeding

By ALBERT E. MUCKLOW, M.D.,
Brooklyn, N. Y.

The desire to present a simple, flexible, yet scientific method of infant feeding prompts this contribution.

We have, for consideration, vitamines, sugar, fat, and proteins; the means for increasing or decreasing any one of these independently of the rest; and the indications for making such variations in their amounts. The thermostabile vitamines are supplied in the milk. The thermolabile antiscorbutic vitamine is supplied in orange juice. The orange juice is started any time, after the first two weeks of age, that artificial feeding is begun and is given in amounts of one teaspoonful daily the first three days, two teaspoonfuls daily the second three days, and so on up to twelve teaspoonfuls (four tablespoonfuls) daily, in which amount it is continued. This supplies a trifle more than Hess's (1) irreducible minimum of an ounce and a half daily, needed to prevent scurvy when boiled or pasteurized milk is used. The advance is made more gradually if gastric intolerance occurs. This is unlikely, especially if only a small portion of the daily amount is dropped upon the tongue every few hours, either between or before the feedings.

Sugar is used in the form of a neutral malt extract. Sugar tolerance is acquired by giving one level teaspoonful of the malt extract daily the first three days, two level teaspoonfuls daily the second three days, and so on up to nine level teaspoonfuls (three level tablespoonfuls) daily, in which amount it is continued. This, according to Dennett (2), is the maximum amount needed. Watch is kept for loose, acid smelling, excoriating stools (3), reducing the amount of malt if these occur. If a desire to economize prompts the use of cane sugar, it may be employed in like amounts.

Fat tolerance is developed by using milk from which have been removed the top eight dipperfuls (eight ounces) the first week, milk from which have been removed the top seven dipperfuls (seven ounces) the second week, and so on until whole milk is used. Watch is kept for soap stools or oily stools, reducing the amount of fat if these occur.

The amount of protein is varied by using a mixture of five sevenths milk and two sevenths diluent (water and malt combined), one of six sevenths milk and one seventh diluent, or undiluted milk. While gradually increasing the percentage of fat and sugar, a high percentage of protein is required. This, as Holt (4) has shown, is not only permissible but advantageous. The amount of protein required is indicated by the weight. A weekly gain of four ounces is desired. Starting with a mixture containing five sevenths milk, we continue with this as long as the infant shows the increase indicated above, subsequently advancing to a six sevenths milk mixture or to undiluted milk as required to maintain this weekly gain.

Ability to increase the protein without materially altering the fat, necessitates a knowledge of the approximate percentage of fat in whole milk and in the bottom milks after various amounts have been removed from the top, as well as a knowledge of the approximate percentage of fat in mixtures composed of six sevenths and five sevenths of these same whole and bottom milks.

Table I, copied from Chapin and Pisek (5), shows the percentage of fat in each of the top eight ounces of a quart bottleful of 4.1 per cent. fat milk, six or more hours after bottling.

TABLE I.—TOP MILKS

First ounce	25.0 per cent. fat
Second ounce	23.0 per cent. fat
Third ounce	19.0 per cent. fat
Fourth ounce	18.5 per cent. fat
Fifth ounce	10.5 per cent. fat
Sixth ounce	4.8 per cent. fat
Seventh ounce	3.4 per cent. fat
Eighth ounce	2.2 per cent. fat

Table II, computed from Table I, shows the percentage of fat in each of the bottom milks.

TABLE II.—BOTTOM MILKS

After removing top ounce	3.4 per cent. fat
After removing top two ounces	2.8 per cent. fat
After removing top three ounces	2.2 per cent. fat
After removing top four ounces	1.6 per cent. fat
After removing top five ounces	1.3 per cent. fat
After removing top six ounces	1.2 per cent. fat
After removing top seven ounces	1.1 per cent. fat
After removing top eight ounces	1.0 per cent. fat

The application of the preceding generalities to the accompanying formulas (Table III), is as follows: Start with a mixture of five sevenths milk skimmed of the top eight ounces. Increase the fat by advancing to a mixture of five sevenths milk skimmed of the top seven ounces the second week, then to a mixture of five sevenths milk skimmed of the top six ounces the third week, and so on. If soap stools or oily stools appear, retrace sufficiently to avoid them. Continue with the five sevenths milk mixtures as long as there is the desired gain in weight. When this ceases, change to a six sevenths milk mixture, selecting a formula with approximately the same percentage of fat as contained in the five sevenths milk formula just left. Continue with six sevenths milk mixtures, increasing the fat by the same weekly advance to a richer formula as when five sevenths milk was used. When again the proper gain in weight ceases, change to undiluted milk, choosing a formula with a fat content corresponding closely to that of the six sevenths milk formula just left. Continue with undiluted milk gradually increasing the fat by the same weekly advance as before, until whole milk is used. In this way flexibility is assured.

The directions to the mother or nurse for preparing and using a formula are: Take two quart bottles of milk which we will call bottle No. 1 and bottle No. 2. Skim off and discard from the top of each of these the number of dipperfuls (ounce dipperfuls) indicated in the given formula. Pour the remainder of bottle No. 1 into a pot with a capacity four times the amount of the formula. This leaves bottle No. 1 empty. Make the remainder of bottle No. 2 uniform by four pourings; that is, by pouring

TABLE III. FORMULAS

5/7 Skimmed of Fat Milk top 8 oz. 0.71%  All of this 11 oz. of this 14 oz. of (water and malt)	6/7 Skimmed of Fat Milk top 8 oz. 0.85%  All of this 18 oz. of this 7 oz. of (water and malt)	7/7 Skimmed of Fat Milk top 8 oz. 1.00%  All of this 25 oz. of this Malt
5/7 Skimmed of Fat Milk top 7 oz. 0.78%  All of this 10 oz. of this 14 oz. of (water and malt)	6/7 Skimmed of Fat Milk top 7 oz. 0.94%  All of this 17 oz. of this 7 oz. of (water and malt)	7/7 Skimmed of Fat Milk top 7 oz. 1.10%  All of this 24 oz. of this Malt
5/7 Skimmed of Fat Milk top 6 oz. 0.85%  All of this 9 oz. of this 14 oz. of (water and malt)	6/7 Skimmed of Fat Milk top 6 oz. 1.02%  All of this 16 oz. of this 7 oz. of (water and malt)	7/7 Skimmed of Fat Milk top 6 oz. 1.20%  All of this 23 oz. of this Malt

5/7 Milk Whole Milk Fat 2.92%  All of this 3 oz. of this 14 oz. of (water and malt)	6/7 Milk Whole Milk Fat 3.51%  All of this 10 oz. of this 7 oz. of (water and malt)	7/7 Milk Whole Milk Fat 4.10%  All of this 17 oz. of this Malt

it into bottle No. 1, back into bottle No. 2, and again into bottle No. 1 and back into bottle No. 2. This procedure thoroughly mixes the milk, as observed by Dr. Harris Moak (6), of the Kings County Milk Commission. Now remove from bottle No. 2 the number of dipperfuls needed, as indicated in the given formula, and add them to the milk in the pot. Fill empty bottle No. 1 with water. Remove from this the number of dipperfuls of water needed and add them to the milk in the pot. Add the requisite amount of malt. Stir until the malt is dissolved. Bring this completed mixture to an active boil and allow it to boil for two minutes. Stir constantly during the entire time the milk is exposed to the heat to prevent burning and scum formation. Let cool. Pour into preserve jars and clamp down, or into nursing bottles and stopper. Stand jars or bottles in the ice chamber of a refrigerator between two cakes of ice. Feed every three hours, allowing the infant to judge the amount of each feeding. The usual rule is an ounce more than the age in months. Half an ounce more in the nursing bottle each time than the infant consumes assures a sufficiency with no danger of over feeding. Use a Chapin dipper to skim off the top milk, removing the first dipperful with a teaspoon to avoid overflowing. Before preparing the food, place the utensils in a large pot and boil them for five minutes, and then do not touch them until the hands have been thoroughly scrubbed with soap and water.

The formulas are all forty-nine ounce mixtures. Other multiples of seven, such as forty-two, thirty-five, or twenty-eight ounces, may be used when the infant requires only such amounts. However, an abundant supply is advisable to provide for the possibilities of a tardy milkman or breakage. If a larger mixture is made up than can be consumed in one day, a proportionately greater amount of malt should be added thereto so that the infant may obtain its daily quota.

Boiling the milk makes its casein sufficiently digestible for the average healthy infant. When the digestive and assimilative functions are at a low ebb, and intestinal putrefactive processes are present, milk fermented with Bulgarian bacilli is ideal. The flocculent curds produced are easily digested and assimilated, and the milk thus fermented is clinically both antiputrefactive and tonic to the gastrointestinal tract. According to Rettger and Cheplin (7), milk fermented with Bulgarian bacilli is not directly antiputrefactive but supplies a pabulum, namely, its contained lactose, acceptable to the bacillus acidophilus, by the multiplication of which the putrefactive bacteria are decreased. Sherman and Lohnes (8) believe that the lactic acid formed during fermentation stimulates the gastrointestinal innervation thereby restoring secretory and muscular tone. Compared with Bulgarian bacilli, bacilli acidophili are not so universally obtainable and their culture in milk is more difficult, the intestines, not milk, being their natural habitat. For these reasons Bulgarian bacilli are more adaptable to the home fermentation of milk. To start the fermentation, a virile commercial fermented milk is employed, virility being assured by selecting a fresh product. On the first day three teaspoonfuls of the commercial fermented milk, and on the subsequent days, instead of the above, three teaspoonfuls of the preceding day's fermented milk are added to a forty-nine ounce milk mixture that has been boiled and cooled. The milk mixture thus inoculated is stirred, poured into preserve jars, sealed and stood in a temperature of 95° F. to 99° F. for twelve hours. It is then rubbed through a fine sieve into a two quart enameled pitcher, poured into preserve jars or nursing bottles, sealed and kept between two cakes of ice. Every few weeks fermentation should be started anew with a commercial Bulgarian milk to exclude any contaminating microorganisms. Milk fermented in this manner, being only moderately acid, is palatable and well tolerated.

The proper temperature for fermentation can be easily maintained in a No. 121-G New Perfection Oven, used ordinarily for baking over the flame of a gas or oil stove. This is of knock down style, hence easily dissembled and portable. To obtain sufficient room, the shelves, heat deflector and bottom are removed and discarded. Into the back part of the oven thus prepared are placed three (two pound) unopened cans of tomatoes or instead of these some other objects of like dimensions and stability. Upon these three cans are placed the two jars containing the inoculated milk and a glass tumbler holding a room thermometer. This elevates the milk and thermometer into the upper, warmer strata. Also place in the oven a lighted kerosene lamp with a flat wick, three eighths, four eighths, or five eighths of an inch wide, depending upon the room temperature. The lamp is not elevated. The oven door contains two glass panels which are easily removed by slipping them upward. By partially or completely removing one or both of these or by partially or completely opening the oven door, more or less cooler air is admitted and more or less check upon the heat obtained. By raising or lowering the flame of the lamp, more or less heat is produced. The correct height of the flame and the correct amount of cooler air to be admitted, may be quickly determined, after which a minor amount of attention is required to maintain the desired temperature.

Constipation is one of the few remaining annoyances of modern infant feeding. Its absence is essential to success. Its treatment consists, in the order of their value, of enemas of plain, warm water (being watchful of the thorough lubrication of the nozzle), liquid petrolatum, and milk of magnesia. These are harmless and may be used, one or all, in any needed amounts, indefinitely.

Calories are of little practical value in infant feeding. The energy outputs, and hence the caloric requirements, of infants vary greatly due to differences in the relative amounts of active protoplasmic tissue and fat, in the mental and muscular activities, in the areas of skin surface (radiating surface), in the clothing, and in the atmospheric conditions (9). Normal nutrition and growth are assured not by considering calories but by supplying in an assimilable form the proper amount of each class of food.

The Artificial Feeding of Infants*

By PHILIP S. POTTER, M.D.,
Syracuse, N. Y.

Nutrition is the most important factor in pediatrics, the largest part of the immense mortality of the first year of life being traceable directly to the lack of knowledge of certain physiological laws regarding the requirements of the growing organism. The elements of food needed in infancy and childhood are the same as in adult life but the relative quantities are different from those required by the adult.

Fats are necessary to supply the animal heat, save nitrogenous waste and increase body weight. Most of the proprietary foods are low in fat and as a result we see many functional disorders commonly seen with rickets. We should bear in mind that in certain conditions the normal amount of fat is badly borne and may do positive harm, rendering it necessary to reduce the amount or replace it for a short time by carbohydrates, particularly in the following circumstances: 1, All wasting conditions depending on disorders of digestion; 2, vomiting; 3, all febrile conditions; 4, during periods of very hot weather. A failure to regard these contraindications is a constant source of trouble in practice.

Carbohydrates are the most important source of animal heat and are capable of replacing the fat waste of the body. The easy digestion of foods consisting chiefly of soluble carbohydrates, such as condensed milk and patent foods, and the rapidity with which children so fed gain in weight, lead to a great misapprehension in regard to their value as foods. The end results of such one sided feeding, if long continued, are almost invariably disastrous.

Proteins are necessary for the growth of the body cells and to replace the continuous nitrogenous waste of these cells. They should not be called upon to supply animal heat, as too strong a milk mixture will severely tax the organs of digestion and elimination. In such an event the products of decomposition may at times be toxic and cause obscure and severe clinical symptoms. On the other hand, a diet too long continued with an insufficiency of protein will cause such symptoms as anemia, cold extremities, feeble muscular power, disinclination to exertion, and various functional nervous disturbances.

Salts are necessary for cell growth and furnish the elements from which the mineral constituents of the blood and digestive fluids are formed and facilitate absorption, excretion and secretion. The most important are the phosphates of lime and magnesium. These are deficient in practically all substitutes for milk.

Water is needed for the solution of certain parts of the food, such as sugar, salts, and some of the proteins, and for the suspension of other proteins and the emulsified fat. It is also needed for the rapid elimination of the waste of the body.

During the time when the child is upon an entirely fluid diet, the addition of much water other than that supplied by the food is unnecessary, but when the number of feedings become less frequent and solid food is given in larger quantities water should be given freely between feedings at all seasons, but especially in the summer.

So much for the physiological laws which must be understood before attempting artificial feeding which is the cause of so much trouble and anxiety, and I might add that even one of large experience often finds himself baffled by the problems which individual cases present. There are infants who, owing to a feeble digestion or individual peculiarities, do not thrive even from the outset upon the usual milk modifications used intelligently.

In dealing with this problem we must remember that at the outset, when slight symptoms of intolerance to the different food elements begin to manifest themselves, we must not regard the condition lightly but must give it our close and continuous personal attention and observation. These conditions do not tend to right themselves and infants' lives are often sacrificed as a result of bad management.

Again we must not confine our whole attention to the feeding itself, but must investigate the daily routine of the infant, for this is frequently found at fault rather than the food prescribed. The food may not be prepared or given according to orders.

Environment is another factor which must be taken into consideration, especially among the well to do. The constant or frequent excitement by visitors or playing with a baby by parents and nurses may result not only in lack of sleep but in disturbances of digestion, often habitual vomiting, though the food itself is proper.

Success in treatment will depend largely upon how accurately one is able to discover the essential cause or causes of trouble and the nature of the disorder of digestion in the case under treatment. Without such knowledge all is haphazard experimentation. Drugs are of little assistance and in most cases they are better omitted altogether.

We should regard every method of modifying milk based upon adequately demonstrated facts concerning the digestion and metabolism of the infant as having its own particular value, and as being particularly fitted to meet the digestive peculiarities of individual babies. We should regard all such methods as constituting our stock of weapons which we need to combat the many difficulties springing from the peculiar chemistry of cow's milk and from the limitless variation in the baby's digestive powers and requirements. We should hail every new research and the practical application to feeding suggested by it, not as a new or better method of feeding babies, but as a new addition to our stock of weapons, a new resource, which will have its particular use in a problem, the nature of which is such that we need all the resources at present available and even more.

In feeding the normal baby the ends to be obtained are: 1, To secure a normal development of the infant that is, a progressive gain in weight; 2, to keep the infant free from all symptoms and signs of indigestion; 3, to develop the digestive powers of the infant.

---

*Read before the Syracuse Academy of Medicine, October 3, 1922.

Two factors must be considered, namely: 1, chemical unsuitability which is overemphasized, and, 2, individual variations which are often neglected.

Every baby has some individual peculiarity. No method of infant feeding supersedes another method, but all have their value, especially in difficult feeding cases. To utilize all the resources of artificial feeding one must be familiar with every method of modifying cow's milk which is in good use, some of which I shall name together with their indications and contraindications.

SIMPLE DILUTIONS OF MILK AND WATER.

Advantage.—Number of different variations by the addition of milk or cream and varying amounts of milk sugar.

Disadvantage.—Makes no attempt to solve the chemical difficulties in the composition of cow's milk fat and mineral salts and in the high proportion of casein by simple dilution.

Indications.—1, Normal infants; 2, cases of fat or carbohydrate indigestion; 3, in all cases in which some special method such as whey proteid or lactic acid milk is not indicated.

COW'S MILK PLUS CEREAL DILUENTS.

Advantage.—Makes finer curds having a colloidal action and a mechanical action.

Disadvantage.—Starch is a readily fermentable carbohydrate. The minimum amount of starch for colloidal action is 0.75 per cent.

Indications.—1, Well infants after the sixth month; 2, sick infants in cases of proteid indigestion latter half of the first year; 3, undigested or green discolored movements.

Contraindications.—Not as a routine under six months.

COW'S MILK MIXTURES PLUS ALKALIES.

An alkali should be ordered with a definite purpose to produce a known result, in a quantity which best accomplishes our purpose and which is expressed in percentages of the milk and cream in the mixture. The alkalies used are lime water, sodium bicarbonate and sodium citrate. There are no indications for the use of any particular one of these alkalies. In some cases lime water works best, in other cases sodium citrate and in another sodium bicarbonate.

Uses.—1, To act on the casein curd; 2, possibly to neutralize the acid products of excessive carbohydrate fermentation in the intestine in which event twenty-five per cent. of the total mixture is used.

Indications.—1, Proteid indigestion with vomiting; 2, persistent vomiting with irritable stomach; 3, green, acid, irritating stools.

Contraindications.—None.

Peptonization.—Object is to predigest the protein overcoming casein indigestion.

Indications.—1, Persistent vomiting; 2, resistant cases when other methods have failed.

WHEY AND MILK MIXTURES.

The original idea was to obtain a closer approximation to human milk. The theoretical advantage is that we can reduce the casein in the food without reducing the total protein. It is the best method of dealing with casein intolerance.

Indications.— 1, Premature babies; 2, very young babies; 3, difficult feeding cases; 4, protein indigestion especially characterized by vomiting; 5, fat and carbohydrate intolerance.

Contraindications.—1, Acute diarrhea; 2, indigestion with green discolored movements.

VARYING CARBOHYDRATES.

These are milk sugar, malt sugar and cane sugar. The majority of the patent foods are carbohydrate foods.

Carbohydrates fulfill two distinct objects, 1, to meet caloric requirements; 2, to be in excess to afford nutriment for intestinal bacteria that is to maintain the normal bacterial flora of the intestine.

Indications.—Milk sugar: 1, In all comparative normal conditions or in conditions in which abnormal intestinal bacteria abound; 2, extra carbohydrate in normal babies; 3, comparatively slight disturbances of digestion; 4, infectious diarrheas due to abnormal intestinal fermentation with proteid decomposition with toxic symptoms; 5, symptoms due to the use of maltose in excessive quantities. Maltose: 1, Weakened digestion, atrophy and malnutrition; 2, difficult feeding cases; 3, routine treatment of chronic indigestion from fat; 4, carbohydrate indigestion from milk sugar or cane sugar.

Cane sugar: There seems to be no evident reason for using this in place of milk sugar in feeding normal infants except that it is less expensive. When babies thrive upon it they do so in spite of it, not because of it.

LACTIC ACID FERMENTATION.

This is obtained by the addition of a buttermilk culture to the milk mixture. It is better not to use fat in a ripened milk because the manipulation of the bottles causes the fat globules to rise together and makes the milk mixture indigestible.

Indications.—1, Difficulty in the digestion of the casein; 2, infectious diarrhea due to the gas bacillus; 3, acute diarrhea with toxic symptoms due to intestinal putrefaction; 4, as a feeding resource in certain difficult feeding cases, e. g., fat indigestion when the usual treatment with low fat, high proteid and maltose not successful; 5, carbohydrate indigestion; 6, green discolored movements when the usual methods of modifying cow's milk causes difficulty.

Contraindications.—1, Vomiting a prominent symptom; 2, habitual vomiting.

PRECIPITATED CASEIN (ALBUMEN MILK).

Made by taking all the casein from a pint of milk and precipitating it with rennet and suspending it in a pint of water and adding a pint of buttermilk.

Advantages.—1, Inhibits putrefactive bacteria if lactic acid is much in excess; 2, carbohydrate intolerance; 3, proteid in a finely divided form and easily attacked.

Disadvantage.—Shotgun prescription.

Indications.—Same as lactic acid fermentation.

BOILED MILK MIXTURES.

Used for possible chemical effect. It makes the casein less readily attacked by the gastric juice and prevents casein intolerance.

Indications.—1, Large casein curds in otherwise normal stools; 2, in very resistant feeding cases.

DIFFICULT FEEDING CASES.

Difficult feeding cases are generally the result of damage to the infant's nutrition by improper methods of feeding. An excess of the food itself, or an excess of one of the food elements, brings about disturbances in digestion which cause important changes in the metabolic processes of the body. From an etiological standpoint they may be grouped as follows: 1. Indigestion from an excess of food. 2. Indigestion from an excess or intolerance of fat. 3. Indigestion from an excess or intolerance of sugar. 4. Indigestion from an excess or intolerance of proteid.

EXCESS OF FOOD.

The symptoms are a loss of appetite, vomiting, colic, increase in the number of stools, failure to gain or loss in weight. The treatment consists in general in cutting down the amount of the food or weakening it. In the acute cases castor oil or milk of magnesia is given and all food stopped for twelve to twenty-four hours. When the feeding is begun the milk is at first diluted one quarter, the next day one half, then three quarters, and finally full strength. Lime water may be added to the amount of fifty per cent. of the milk and cream in the mixture. If vomiting has been pronounced skim milk is to be used in the dilutions mentioned above. In cases of diarrhea the milk is boiled. In the chronic cases the strength of the food is reduced until the baby is free from symptoms and if the gain in weight is not satisfactory the food is gradually strengthened.

EXCESS OF FAT.

The three main symptoms are vomiting, abnormal stools, and failure to gain in weight, or more often a progressive loss. The vomiting usually occurs between feedings or at the end of the feeding period. It is strongly acid and has a sour odor. Sometimes it is creamy in appearance. The stools contain many soft curds often accompanied by mucus. They may be creamy in appearance or loose, green and so strongly acid that they irritate the buttocks.

Chronic cases show large hard grey or white crumbly stools which sometimes are so dry that they roll off the diaper.

Loss of weight is marked.

In acute disturbances there is a rapid loss of weight and high fever. Rapid and deep respirations appear with stupor or restlessness and cherry red lips. This is an acidosis or what we term a "fat blow up."

Chronic disturbances manifest symptoms of rickets or those of a spasmophilic diathesis. The disturbance is so marked that we get the picture of marasmus or infantile atrophy.

In the acute cases all the fat must be taken out at once and in a few days again cautiously added checking it up by the observation of the symptoms and examination of the stools microchemically. If human milk can be obtained it should be utilized and in some instances it may even be necessary to skim it. If the case is desperate three to four ounces of a five per cent. dextrose solution is given intravenously.

In the most severe chronic cases diluted skim milk is used. In the less serious the fat must be reduced materially. In moderately severe cases it should be reduced at least to one per cent., in the mild cases two per cent. is probably sufficient.

When the stools begin to show no evidence of fat indigestion, the fat may be cautiously increased not to exceed 0.25 per cent. at a time and always controlled by a microchemical examination. Several days should intervene between changes.

The carbohydrate and proteid should be increased if possible in order to keep up the caloric value.

The sugar should not exceed seven per cent. and if there has been a previous sugar indigestion it should not exceed five or six per cent. Dextrimaltose is preferable to milk sugar because it is less fermentable and is more easily absorbed.

The proteid should be low at the start and gradually increased, stopping short of the limit of intolerance. Whey milk mixtures should not be used because of the large amount of whey salts. We might say that one could start off with a simple dilution of skim milk and water using one part of skim milk to three of water and gradually strengthen this mixture by adding an ounce of skim milk and taking out an ounce of water. Later on when fat tolerance is established whole milk and water dilutions may be used. In the mild cases half milk and half water may be used as a starting point. Enough milk sugar or dextrimaltose may be added to bring the sugar to the desired percentage.

EXCESS OF CARBOHYDRATES.

Indigestion from an excess of carbohydrates may be due to an excessive amount of either starch or sugar. The sugar at fault may be any one of the sugars—milk sugar, malt sugar, or cane sugar. The general symptoms of indigestion from this are vomiting, abnormal stools, excessive gas formation, and loss of weight. The vomiting takes place between feedings. It is watery, acid, and has the characteristic odor of lactic, acetic or butyric acids. The stools are loose or watery, green, acid and often contain more or less mucus. These acid discharges are very irritating to the buttocks, excoriation of the buttocks and genitals being one of the commonest signs of indigestion from an excess of carbohydrates. Loss of weight may be absent in the mildest of cases but is marked in the severe cases. Flatulence, colic, abdominal distention, and the passage of quantities of gas from the rectum are symptoms often seen. The extreme condition of malnutrition described as infantile atrophy may result.

The following are the main peculiarities of the symptoms caused by the various carbohydrates:

Lactose is the sugar most likely to produce acute symptoms. The stools are practically always green and very irritating. Flatulence and colic are less prominent.

Cane sugar is less likely to produce acute disturbance. Babies are likely to gain in weight on cane sugar but become pale and flabby.

Dextrimaltose preparations rarely produce acute exacerbations. The stools are often dark brown and have an acrid odor. Vomiting is apt to be more prominent and has the odor of butyric acid. Flatulence and colic are common.

Starch produces chronic symptoms only. Vomiting is rarely seen. The stools may be constipated, dry, brown and alkaline in reaction. When loose they are brown and resemble mucus. The principal symptoms are pronounced colic, flatulence and abdominal distention.

Babies fed exclusively on starchy foods may seem to thrive for a time in that they gain in weight, are of a fair color and seem lively and well. Careful examination even at this time will show, however, that there is an exaggerated tonicity of the muscles, and in a few weeks they may begin to lose in weight and color, their muscles become flabby, and gradually they take on all the characteristics of the starved atrophic infant.

The treatment is dietary from the start. The first step is to change the kind of sugar used. If milk sugar or cane sugar has been used, a dextrimaltose is substituted. If maltose is at fault the change should be made to milk sugar. If changing the kind of sugar does not relieve the symptoms, providing the sugar is not over seven per cent., then there is intolerance to sugar in general and it must be reduced to the point of relieving the symptoms. If the sugar has to be cut so low that the baby does not gain in weight, a precipitated casein or albumin milk may be used.

INDIGESTION FROM EXCESS OF PROTEIDS.

The principal effect of excessive protein in the food is confined to the gastrointestinal tract. There are vomiting, colic, abnormal stools and loss of weight. The vomiting occurs shortly after eating and usually contains large soft or very tough leathery curds. It has very little odor. The stools are increased in number, loose in consistency, brownish in color and rather sticky. They are alkaline and musty or foul. Loss of weight is comparatively slight. In the type characterized by large curds, nutrition is usually not disturbed. The treatment consists in the earlier months of infancy of using a whey milk mixture; in older children of reducing the amount of the proteid but not less than 1.5 grams to the kilo of body weight. When vomiting is the chief symptom one should try the addition of one of the alkalies to the milk modification.

In closing, let me say that just as the highest aim of medical art should be directed to the province of preventive medicine, so the highest and most practical branch of preventive medicine should consist of the study of the best means for starting young human beings in life and the objects in view should be to preserve these young infants from the perils which surround the early hours of their existence and to give them strength and vigor to resist the attacks which must inevitably be made upon their vitality.

213 WESTMINSTER AVENUE.

A Practical Consideration of the Pirquet Feeding Method*

Simplified for Children Up to One Year of Age

By HARRY APFEL, M.D.,

Brooklyn.

It will not be amiss at the start to make the statement that the method of feeding as it is being advocated by the Vienna School has never been interpreted correctly, and that is the chief reason why my first report (1) was received with a good deal of skepticism and opposition. The originator of this method, Professor Pirquet, during his recent visit to this country, was reluctant to mention it even in public, for, as he said, "I like the American doctors too much to fight with them," and so he spoke on tuberculosis instead.

My plan here is to give only a brief outline of the socalled nem system, as the Pirquet system is called, with a consideration of its practical application in office and clinic, for children up to one year of age.

A child's food requirements will be the same whether calculated in terms of nems or calories. Whereas we say a given child should get from fifty to sixty calories to the pound of body weight, we calculate the food requirements for each child by measuring the sitting height of the child regardless of its weight or age and we know exactly how much food it requires.

PRINCIPLES OF THE NEM SYSTEM.

1. Whatever food we employ, we must compare its nutritive value with that of mother's milk, the basic food. I contend that mother's milk, which answers satisfactorily to all body requirements for the growing child during its first year of existence, must consist of correct and proper food constituents, hence the term nem which is composed of the first letter of each of the three words, *Nahrung Einheit Milch* (nutrition similar to milk), or milk nutrition value (Nobel).

2. The amount of food one requires and will be able to assimilate in the course of twenty-four hours is in exact proportion to the square surface of one's intestinal tract.

3. If food in excess of this quantity is ingested it will not be absorbed, but will pass out of the intestinal canal as so much waste matter.

4. The square surface, *siqua,* of the intestinal canal can be obtained from the sitting height (*sitz höhe*) of a given patient, employing the metric system.

5. Studying the various measurements of the digestive tract as worked out by Vierordt (2), Gundobin (3) and others, Pirquet came to the conclusion that the square surface of the intestinal canal is equal to the square of the patient's sitting height. The sitting height is obtained by measuring the distance from the surface the patient sits upon to the topmost part of his skull (patient sitting undressed). In the case of an infant, it is best to lay the patient on its back, the thighs flexed with buttocks against a board, measuring from this board to the top of the patient's skull. The rule follows: sitting height square (*siqua*) is equal to the square surface of the intestinal canal.

---

*Read by invitation before the twenty-third annual meeting of the Lake Keuka Medical and Surgical Association, July 6, 1922.

6. According to the Vienna school, it matters little what food elements—carbohydrates, proteid, or fats—we chose for our patient, as long as the total food contains as many nems as the number of square centimetres of the patient's sitting height, the food quantity being weighed in the metric system; one gram of mother's milk, the basic food, is equal to one nem, which is our basic measure. That the prescribed food shall contain at least ten per cent. and not more than twenty per cent. of the proteids is the only condition that the author makes.

The author goes further and says that the nem worth of every individual is not absolute but varies between a maximum and a minimum level, the latter being the quantity of food that the individual requires when he is in a state of rest, in bed and kept warm. This figure is three tenths of the sitting height square of three decinem siqua. This measure may be recommended at certain times when body exercise is very limited or when it is necessary to give the digestive tract a rest, and only for a limited time. The former is 10/10 of sitting height square or ten decinem siqua. Neither is this amount of food always employed, it is only employed in exceptional instances, and when putting on of weight is essential, for instance, in the case of a marasmic baby. There is a point between these two extremes, maximum and minimum, which the author has named the optimum scale, and which is an arbitrary point. This is from five to seven decinem siqua. This measure is the one recommended in the average case, for the reason that it includes three tenths minimum, plus one tenth for exercise, one tenth for growth and one tenth for taking on of weight, which makes a total of from five to seven decinem siqua.

The practical application of this is as follows: For instance, a baby's sitting height measures forty-five cm. The square of 45 is 2,025, in round numbers 2,000. Hence, 2,000 nems is the maximum food requirement for the twenty-four hours. Seven tenths of this sitting height square is 1,400 nems, which is the optimum food requirement usually employed. Three tenths of this sitting height square equals 600 nems, the minimum food requirement, which is rarely employed and only for short periods, this quantity not being sufficient for a growing child. It will just be sufficient for the child to exist upon.

1 gram milk=1 nem.
For maximum figure 2000 grams of milk=2000 nems.
For optimum figure 1400 grams of milk=1400 nems.
For minimum figure 600 grams of milk=600 nems.

If we wish to feed the child on, let us say, cereal, milk and sugar:

Gms.	Nems
Milk	800=800
Farina	60=300
Sugar	50=300
Total	1400
Farina	1 gm.=5 nems

It is necessary to consult the table for the nem worth of each article of food until one becomes familiar and remembers these figures by heart.

Right here is where the nem system ends. The concentrated food formulæ or whole milk and sugar formulæ which have been employed by the Vienna School are still in an experimental stage and should not be spoken of as part of the nem feeding method, although in the hands of Schick they have proved successful. Nevertheless, he himself counsels that one should not employ such mixtures indiscriminately for all children.

One of the chief objections to this method of feeding is the mathematical calculation it requires. But owing to the fact that whether we calculate in nems or calories we always think in terms of the individual case, and inasmuch as the optimum nem worth is more or less approximate, hence we cannot figure the food needed down to a fraction. We can if we choose make use of a table giving the food requirement for a given sitting height. Such a table has been compiled and adopted for use in the Pirquet outpatient clinic for the purpose of saving time.

One may still further simplify the process by consulting a table containing average sitting height for a given age. Knowing the age of a child, by consulting this table one learns at a glance the average sitting height and below it the already calculated amount of nems for the given sitting height, per one tenth of a siqua. We simply multiply the equivalent of one tenth siqua by five or seven, or as many nems as we may wish to give and we have the total number of nems required for a given child for twenty-four hours.

Feeding Scale adopted from Pirquet's Ernährungs Schule

Month	1	2	3	4	5	6	7	8	9	10	11	12
Siqua	34	35	36	37	38	39	40	41	42	43	44	45
							.1 Siqua					
Nem	100	120		140		160			180		200	
							.7 Siqua					
Nems	700	840		980			1120		1260		1400	

CONVERTING OUNCES INTO GRAMS.

Allowing that thirty grams are the equivalent of one ounce and a tablespoon being the equivalent of fifteen grams, we can easily figure out the food quantity in ounces or tablespoons and readily convert them into grams.

Example.

Milk 1 oz.=30 gms.=30 nems.
Sugar 1 tablespoon=15 gms.=90 nems.
1 gm. milk=1 nem.
1 gm. sugar=6 nems.

We all know what a responsibility everyone feels when called upon to direct a baby's feeding, especially when the baby is in its infancy, or still worse, when it happens to be a premature birth.

The doctor usually begins to calculate in terms of percentage feeding, using top milk, adding as many ingredients as would appear in a good reliable prescription twenty years ago. The more modern man will order a very much diluted milk. For example, we have been advocating to begin with one third milk to two thirds water with the result that in order that the child should get the required number of calories (nems) it must take very large quantities of the mixture.

Here is the outstanding feature of this feeding method as inaugurated by Schick, namely, to furnish the required amount of food in as concentrated a form as possible. The more obstinate your patient is to its feeding, the more concentrated should the food be made.

These investigators abroad, notably Schick (4), have shown conclusively that even the premature infant will tolerate whole milk plus seventeen per cent. of cane sugar and that there is no reason for starving a newborn infant on an infusion of cow's milk. This statement I can substantiate from personal observation with the numerous newborn infants so fed at the Schauta Clinic, Vienna, and a number of newborn infants fed on fairly concentrated milk and sugar formulæ in my office practice, as well as on my service in the Brooklyn Hebrew Maternity Hospital. At the former institution every infant is put on a whole milk and seventeen per cent. sugar formula one day after birth, and is so fed until the mother's breast can supply the required amount of nourishment for the baby.

I have found it practicable to divide my feeding children into two groups. 1. The healthy children where mother's milk is unobtainable. 2. Children suffering from some digestive disorders, such as pylorospasm, severe vomiting, and poor appetite. For the healthy baby there is no special reason for concentrating its food to any extreme, and furthermore, a little extra water will not harm. A healthy infant with a good appetite will not be satisfied with small bulk, hence, while we now give concentrated milk and water mixtures, we do not give whole milk and seventeen per cent. sugar to babies under five months except for special reasons. In the case of the sick baby we are anxious to see that it takes all the food it needs in as small a bulk as possible, hence we concentrate the food as much as possible. I can state with firm conviction that an infant will fare much better on a somewhat concentrated food than on an infusion of milk.

The question may be asked what would one consider a concentrated milk formula:

1 week to 2 months—½ milk and 2-3 tablespoons sugar to the total milk mixture.
2-3 months—¾ milk and 2-3 tablespoons sugar of the total milk mixture.
5-12 months—whole milk and 2-3 tablespoons of the total milk mixture.

For exceptional cases whole milk and sugar even at three months.

Case 1—Baby D., eleven weeks old. The child vomited after every feeding, and had five or six watery stools daily. One feeding formula which had been used was as follows: Milk, ten ounces; water, eleven ounces; dextrimaltose, two and a half tablespoons. On this formula the child lost weight steadily. It was then put on a formula consisting of skimmed milk, thirty-one ounces; water, five ounces; milk sugar, one fourth ounce, with the same result. Birth weight was seven pounds, present weight, eight pounds five ounces. Examination showed an infant undersized with a mild degree of hydrocephalus.

Treatment.—For this child's age the average sitting height:

(Si.)=36 cm.
.1 siqua=120 cm. (see scale).

This infant being much under weight we give him 8/10 siqua.
.8 siqua=960 nems required for twenty-four hours.

FORMULA PRESCRIBED.

Whole milk, 30 oz.x30 gms.=900 nems.
Barley water, 12 oz.=12 nems.
Cane sugar, ½ tblesp.=42 nems.
954 total nems for twenty-four hours.
(1 oz.=30 gms.)
(1 tblesp.=15 gms.)
(1 gm. sugar=6 nems)
Divide into twelve feedings; 3½ oz. q. 2 hrs.

Results: After two weeks, two stools a day, slept well, no vomiting, weight nine pounds three ounces (gain fourteen ounces).

RÉSUMÉ.

We are firmly convinced that the premature infant, as well as the newborn baby, will thrive much better on more concentrated milk mixtures. Vomiting is less frequent than with the more dilute milk formulæ. In cases of severe and obstinate vomiting whole milk not diluted is especially recommended owing to the fact that the quantity can be materially lessened. A rational method of calculating a patient's food requirements as well as its nutrition value. For children with poor appetite it is of great advantage, inasmuch as the quantity can be materially diminished.

TABLE OF FOODS AND THEIR NEM WORTH.

(*Figures on right hand side denote proteid content*)

Nem in 1 gram					
12	Butter	0		Beans	2

182 NEW YORK AVENUE.

Febrile Conditions in Children*

By HYMAN GOLDSTEIN, M.D.,
New York,
Visiting Pediatrist, Day Nursery Daughters of Israel; Assistant Physician, Children's Clinic, Lenox Hill Hosp. O. P. D.; Chief Visiting Physician, Home of the Sons and Daughters of Israel.

The problems involved in febrile conditions of children are many. Hyperthermia and its results are more or less dependent upon the individual peculiarities of the one affected, of the cellular metabolism and the excitability of his nervous system. This explains the ease with which temperature fluctuates in children from the slightest cause.

In all cases of fever we get certain secretory, circulatory and nervous disturbances since body temperature represents naturally the balance between heat production and heat loss. The production of temperature is affected mainly in the muscles by the oxidative processes which are constantly ensuing there. Fever may be caused by infectious processes; parenteral injection of foreign protein; excessive destruction of protein substances in the body itself; action of certain drugs and injury to the base of the brain or lesions of the upper levels of the spinal cord.

There is a specific destruction of protein going on in the body during fever, evidenced by excessive amount of creatinine, of purin bases, and incomplete hydrolyzed proteins or proteoses in the urine. This causes a considerable loss of nitrogen and hence disturbs the nitrogenous equilibrium. Therefore in fever patients our object should be to maintain nitrogenous equilibrium by feeling large amounts of carbohydrates. The increased combustion processes occurring in the tissues are responsible also for the increased excretion of uric acid. Hypoxanthin and its precursor inosonic acid in large amount in the muscular extract is an important source of endogenous uric acid. Lithia salts and also bicarbonate of soda should be administered in febrile conditions, the former to prevent uric acid concretions from forming and the latter to protect against possible acidosis. Another interesting metabolic change in fever and also from a prognostic viewpoint is the salt balance. This is studied by observing the amount of sodium chloride excreted by the urine. If it is much diminished it may be a danger signal. Salt retention is more marked in certain fevers than in others, and essentially different than the salt retention in nephritis. In the latter the concentration of chlorides in the blood is considerably increased, whereas in fever it is markedly diminished. Increased retention of creatinine in the blood in nephritis is a danger signal. Fever is but a symptom of an abnormal condition in the individual, the root of trouble which must be found. It is not so often easy to get at the source, as I will show in the following cases:

REPORT OF CASES.

CASE I.—S. M., five years of age, was referred to me during March, 1920. She had a slight follicular tonsillitis involving the right tonsil; tem. 103° F. Chest, ears, eyes, skin and glands negative; abdomen revealed rigidity of the right rectus muscle, marked tenderness at McBurney's point and a definite round, painful mass in the same region. Her chief complaints were fever, abdominal pain and nausea. Rectal examination showed also tenderness at the right side. Blood examination showed 21,000 leucocytes, ninety-two per cent. poly., and eight per cent. lymph. This picture was tentatively one of acute appendicitis with abscess. The latter diagnosis was confirmed by the consulting surgeon. Because of the happy or cheerful expression of the little patient and the sthenic pulse I looked for another interpretation of the symptoms and ordered another specimen of the blood and a catheterized specimen of the urine to another laboratory. In the meantime an enema was given with an excellent result. The author called the surgeon's attention to this, who remarked that the abscess must have opened up into the cecum and that this was an admixture of pus and feces. I could not agree with this explanation, for two reasons, first, that the child appeared too well generally to account for a ruptured abscess in the gut and, secondly, that with the result from the enema the abdominal mass disappeared. The fever still continued. The second laboratory report showed 7200 white blood cells, sixty-eight per cent. polymorph. and thirty-two per cent. lymphocytes. The urine was loaded with leucocytes and clumping, little albumin, acid, no casts but many colon bacilli. The diagnosis of pyelitis was then evident. Long continued treatment with urotropin in acid media alternating with the alkaline treatment from time to time, modified lactovegetable diet and bacilli acidoph. tablets cleared up the condition. She is quite a healthy youngster now.

CASE II.—A. J., two years of age, seen in consultation February, 1921. He was dressed and playing in the room. His face was flushed and temperature 104° F. He was in fever from time to time for several weeks and his case diagnosed by many to be teething, indigestion, influenza and finally brain fever. The latter alarmed the mother and the author was consulted. Outside of being a little tired, he complained of nothing and physically he was normal except for the temperature. I had him urinate and boiled a specimen which showed a marked amount of albumin. He was placed on acid urotropin treatment. In the meantime a more thorough laboratory examination of the urine was made. The findings confirmed the diagnosis of pyelitis. He responded well to treatment. Occasionally during the following six weeks for a day or two he would have a subnormal temperature in the morning and a high temperature towards evening. The pus in the urine cleared up. Three months later the writer was called in again and found the patient's head bandaged and got the following history. The family physician recommended an ear specialist who pierced both drums with no result. A week later the right mastoid was operated upon and much pus came through, and the wound took a few weeks to heal up. The fever still continued in remissions. The adenoids and tonsils were removed but the temperature still remained up. The child began suffering from asthma now. Removal of the mattress, pillows and blankets did no good and also all protein sensitization tests were negative. The child was also frequently subject previously to attacks of bronchitis. The urine was again loaded with pus. He was placed again on acid urotropin treatment. Thyroid and pituitary extracts in small doses relieved his asthmatic attacks. His urine became clearer. I observed that the walls of the rooms were dripping and that there was a very damp, foul odor. I ordered him to be removed to dry living rooms and he was transferred to his aunt's home where he had no attacks of the asthma or fever. When at home it returned. Change of address to a steam heated apartment relieved him. Since then he does not suffer. Aided by the other treatment the kidneys cleared up.

---

*Read before the Yorkville Medical Society, December 20, 1922.

Case III.—J. K., three years of age, was referred to me by Dr. Schutz. Upon examination I found the patient playful, face flushed, slightly nauseated, temp. 103° F., physically negative except for tenderness at McBurney's point and slight rigidity. Rectal examination revealed nothing for the child resisted too much. From the general aspect of the case I diagnosed it as one of a general intoxication, the source of which should be sought. The urine showed many leucocytes and clumping with acid reaction while the blood count and differential were negative. Hence pyelitis was the source of trouble and proper treatment cleared up the condition.

Case IV.—Dr. C. N. Gelber consulted me in reference to Dr. M.'s baby, whose ear drums he had lanced. They had drained well but, in spite of this, the child was running a temperature. Upon physical examination I discerned a definite pneumonic lesion, although small at the left base, peripheral in type. Not until the third day thereafter did the lesion become more distinct, meaning that the complete area to the bronchus had consolidated causing the physical signs to show up clearly. The child made an excellent recovery.

Case V.—An infant eight months old was brought into my clinic at the Lenox Hill Hospital with a history of falling upon a nail that stuck in the skin behind the right ear and which was removed. The following day the temperature was 103° F. and the baby had a slight diarrhea with slimy green stool which in spite of this was diagnosed as teething. Physically the head, special organs, reflexes, skin, glands, chest and abdomen, except for a little rigidity, were negative. The pharynx was congested and tonsils submerged with exudate oozing from its crypts. There seemed to be an acute tonsillitis and gastroenteritis. For further study the author referred the child to the hospital division. When admitted the next morning the child was normal except for a slight congestion of the pharynx and cryptic exudate but normal temperature. In fact, the admitting physician was reluctant to admit the child. The same evening the temperature rose to 104° F. On the third day the lower and upper extremities developed a flaccid paralysis and the child was in a semicomatose condition. During the next two days the temperature was subnormal in the morning and high in the evening. The spinal fluid was blood stained and other laboratory examinations revealed little. That evening the temperature rose to 106° F., the child's heart collapsed, but with urgent emergency stimulation began beating feebly and soon after the infant died. An autopsy showed a cyst of the lateral ventricle on the right side with compression and edema of the cerebral convolutions, and a little fluid in the pericardium and pleura. The collapse was undoubtedly due to the sudden filling up of the cyst in the lateral ventricle and the pyrexia because the lesion approximated the region of the heat center in the brain.

In Cases I and III it will be noticed that the symptoms were panoramic and not pathognomonic in their arrangement. In appendicitis we usually discern first diffuse abdominal or umbilical pain, vomiting, fever, then localized pain in the right iliac or McBurney's region with zone tenderness and often retained enema, the latter as a result of the peritoneal irritation splinting the intestine. This order of symptoms did not occur in these cases. Secondly, the facies and pulses were not suggestive, and thirdly, do not place too much reliance upon the laboratory findings alone which at times is very inaccurate and misleading, as is well shown in the first case. Case II was undoubtedly one of low resistance with malnutrition predisposing this child to infection due to the effects of the high humidity or dampness in the living rooms with resultant systemic infection most likely of the influenza type thus affecting this human barometer. Case IV points out to us the necessity of careful physical examination of the chest. Unexplainable fever, rapid respirations with dilating nostrils when breathing should put one on guard as to the possibility of peripheral pneumonia formerly known as central pneumonia, being present, even if early signs cannot be detected. Case V is very interesting both for the general practitioner and the consultant. Don't be overanxious to lessen the load by telling the mother "your child is teething or nothing is the matter with your child—it is just a little of this or that, etc., or to criticize the other physician before you, who, perhaps upon calling, found the child perfectly normal, although a dangerous condition was brewing within, as in this case when the child was first admitted in the hospital. A good reputation may be undone over night or cause one to become involved in a complicated law suit.

You will notice that I have purposely left out a description of other known febrile conditions, i. e., typhoid fever, malaria, meningitis, tuberculous conditions, rheumatism, dysentery and the contagious diseases most are familiar with. However, it will not be amiss here to caution against mistaking rubella, anaphylactic serum and food protein rashes for scarlet fever. In scarlet fever, aside from the characteristic faucial angina and tongue you will notice an almost chocolate brown line at the elbow, pit of the axilla, wrist and groin at the flexor surfaces because the rash has a tendency to become more confluent and thick near the folds of the skin. In rubella or German measles, besides the mildness of the rash and other symptoms, the posterior cervical glands are enlarged.

When children complain of growing pains, asthenia, weakened cardiac impulse and palpitation, frequent sore throat, choreic movements and nervous irritability, think of rheumatism. Tuberculous bronchial glands will often explain many conditions that are frequently overlooked. Typhoid fever, malaria, cerebrospinal meningitis and general tuberculosis run an atypical course in children. The careful physical examination, careful history and course of the disease will help considerably to diagnose the case. Tuberculous meningitis must be thought of particularly in young infants and often is of the bovine type. Examination of the ventricular fluid may help where the spinal fluid is hard to obtain. This may also be adopted as the route for therapy.

PULMONARY CONDITIONS IN CHILDREN.

Of pulmonary conditions in children bronchopneumonia is prevalent before the fourth year because of the greater number of cases of diphtheria, pertussis and exanthemata at this age after which year lobar pneumonia becomes the predominating type. In most instances the consolidation is small and involves but a very little area of lung tissue at the periphery not reaching any part of the bronchial tree and rarely giving any physical signs, except the positive subjective symptoms. This condition is known as peripheral pneumonia formerly regarded as central pneumonia which is really a misnomer. The objective findings here may be just a little distant bronchial breathing or increased fremitus; a little rough breathing or, few râles heard either in the small of the back between the wings of the scapula, pit of the axilla or sixth interspace postmammary line, as compared with the healthy side. Early stimulation in pneumonia of children is essential. Dr. A. L. Goodman and Dr. J. S. Leopold are getting excellent results and a surprisingly low mortality rate in their cases at the Lenox Hill Hospital and the author finds it so in his cases from such treatment. I would strongly caution against the injudicious use of digitalis in pneumonia. When indicated give a big dose and don't depend upon it as the only stimulant. While digitalis energizes the systole it prolongs the diastole of the heart, and, its accumulated action may cause heart block, in which condition the tired cardiac muscle cannot get back to systole and hence a patient getting along well may suddenly collapse because of this. Other stimulants should be used singularly or combined, such as caffeine sodium benzoate, strophanthus, strychnine, convalleria, camphorated oil, sparteine along with ammonia salts, guaiacol carbonate, etc.

The individual characteristics must be considered in each case, the symptoms as they appear in their chronological order has significance and must be analyzed as such, as well as interpreted *per se*. Therefore an accurate history in every case is essential. The textbook is a guide, but not a book of labels from which one can take a label and paste it onto the patient giving him this or that disease. In other words generalize the disease (that is what the textbook is for) but individualize each case.

A Comparative Chemical and Clinical Study of Boiled Butter and Cream in Infant Feeding

By HARRY LOWENBURG, A.M., M.D.,
Philadelphia,
Pediatrist, Mt. Sinai Hospital, Jewish Hospital, Etc.

The need of the growing organism for fat is no longer a matter for discussion. The etiological influence of bovine butter fat in many cases of acute alimentary disturbance occurring in the artificially fed suckling also appears to be well established. Between these two antithetical activities, the one constructive, the other destructive, the pediatrist and the dietitian have labored to find a happy solution to the problem of how best to supply this much needed ailment so that it will be digested and assimilated without producing irritation with resulting loss of weight, which is usually the condition for which it was originally added to the food ration. All sorts of means have been devised to change physically or chemically the character of butter fat as it is found in cow's milk or to determine upon a suitable substitute for it. Pancreatization, the complete or partial elimination of fat by the use of skim or partially skimmed milk and the substitution for the aliment thus lost of extra carbohydrate, have been the means most frequently proposed and are often, within certain limits, productive of splendid results, providing other measures are at the same time employed to provide antirachitic factors. I have fed hundreds of infants upon diluted skim milk mixtures and am therefore convinced from this experience that it can be done successfully using surprisingly weak dilutions. However, it may be readily admitted that the method is a questionable means toward a good end and leaves much to be desired in order to combat certain biochemical deficiencies which occur in spite of the progressive gain in weight, as for instance rickets, as just stated.

The experience and opinions of a host of technical observers prove that fat is essential to the growing child. Nevertheless, having knowledge of its power for harm, many have underfed with this substance. Others, unmindful or uninformed of its possible baneful influence, continuously overfeed with it. This in its last analysis amounts to the same as underfeeding, for the resulting acute alimentary disturbance, as manifested by vomiting and diarrhea, causes the imbibed fat to be lost per primam viam and the organism assimilates none or little of it. It becomes plain, therefore, why many infants who are losing weight on high fat mixtures will start to gain when fed low fat, as represented by skim milk dilutions, because they absorb and assimilate that which they imbibe. However, when it becomes necessary to increase the fat, it cannot always be accomplished by the addition of cream, without producing an acute upset. The problem has been, therefore, to find a way of supplying this needed fat in sufficient amount and in a form acceptable to the digestive apparatus. This seems to have been solved by the butter-flour mixture of Czerny and Kleinschmidt. This consists in adding, according to the weight of the infant, one third or two fifths of boiled cooled milk to a stock solution which must contain equal parts (twenty grams each) of boiled butter and flour, fifteen grams of cane sugar and three hundred c. c. of water. I have employed the butter-flour mixture in what appeared to be suitable cases and largely with good results.

The difficulties encountered it is not necessary to discuss here, as the purpose of this communication is simply to detail my experience with the simple addition of boiled butter, instead of cream, to ordinary skim milk dilutions containing nothing more than skim milk, water, sugar and salt, with or without the addition of starch in the form of a cereal decoction or of a previously indeterminate amount of boiled and baked brown pulverized flour ball containing or not a small amount of extract of pancreatin and bicarbonate of soda. The addition of flour ball is mentioned to call attention to the fact that it is an age old remedy of extreme usefulness and corresponds in a sense to the browned flour used in the butter-flour mixture of Czerny and Kleinschmidt and antedates this procedure by probably a century or more. The reason why it is possible to feed the large amount of fat as represented in the butter-flour mixture and not feed the same amount as represented by cream or top milk added to a formula which also contained starch, has not been stated definitely by the large number of clinicians who report their experiences with this method. Some have conjectured that it is due to the driving off of the volatile fatty acids and others that it depends upon the browning of the flour in the process of baking. The latter seems untenable as browned flour as represented by the prepared flour ball has been often employed in mixtures wherein the fat was represented by top milk or cream and the tolerance of the infantile digestive apparatus for the extra fat was not improved.

The matter appeared to be of sufficient importance as to merit investigation and the problem was first attacked clinically and later confirmed by chemical study. The theory that the tolerance for bovine butter fat, as found in the butter-flour mixture, depended upon the equality of proportion between the amount of flour and that of butter being maintained, did not work out clinically for I have often found it necessary and helpful to reduce the quantity of flour on account of extreme constipation and gaseous distention. After all, while the infantile digestive apparatus is the last arbiter as to the digestibility and assimilability of any formula it seems a bit too much to credit these organs with brains and temperament that would cause them to reject food simply because it did not correspond to a man made rule that such and such ingredients must exist in equal proportion.

At first butter boiled slowly for five minutes as directed by Czerny and Kleinschmidt, in measured quantities instead of cream, was simply added to skim milk dilutions without reference to whether they contained flour or starch in any form. In the beginning small amounts were added, such as a quarter of an ounce to a thirty or forty ounce mixture. Gradually these quantities were increased until one and a half to two ounces were added to a thirty or forty ounce skim milk formula. It was found to agree surprisingly well, as indicated by the protocols of the thirty-eight cases occurring in private practice and herewith submitted.[1]

The number of cases studied it is true is small, but it is thought that they constitute a sufficient nucleus to warrant further investigation and to indicate with a certain degree of probability that the success lay in the boiling of the butter.

Gain in weight was maintained in nearly all cases, in one in spite of a severe eczema; in one case a gain of sixteen ounces was recorded in four days. One infant gained slowly and had several periods of stationary weight because of an unexplainable yet persistent anorexia which seemed to date from birth, and was the cause of removing the baby from the breast. In three or four cases fever developed, due to otitis media or grippe, and in one case to pink eye. All these infants suffered a temporary loss of weight or remained stationary. Gain, however, was inaugurated as soon as the parenteral infection subsided. Three babies also showed slight dyspeptic symptoms which subsided when they recovered from the infection. One, running a temperature as high as 105° or less for two or three weeks, due to pyelitis, ceased to gain and had some temporary digestive disturbance. Its bowels, however, speedily became normal before recovery simply by reducing the entire strength of the food one half without removing the butter. After complete recovery this infant gained eight and a half ounces in three days. In another instance failure to gain was thought to be due to extreme poverty and ignorance as to the general care of the infant. Abnormal digestive phenomena were absent, and in many instances vomiting ceased.

In two cases of partial pyloric obstruction, in which the infants were doing well on thick farina the boiled butter was added to the cereal without a renewal of the vomiting. In two instances, diarrhea with temporary loss of weight, was recorded. Both these babies suffered a change in milk by reason of removing from the city to the country. The stools in the remainder were normal and even in some cases constipated. The reaction was invariably feebly or markedly alkaline. In two other cases with diarrhea and in which the usual treatment had been given consisting of a hunger period of saccharated tea for twenty-four hours followed by a protein milk, after constipation had occurred, the boiled butter was gradually added to the protein milk mixture without causing a renewal of the trouble. It was thus clinically determined that this substance was tolerated in a variety of conditions where from previous experience it was felt that the addition of cream would have been a hazardous undertaking. The tolerance for boiled butter with or without the addition of starch having thus been determined clinically it was decided to ascertain why boiled butter possessed this advantage over raw butter and cream.

Before proceeding further it is necessary to emphasize two phases of this subject which in no way invalidate the statement that the infantile digestive apparatus can digest and assimilate pure unaltered boiled butter. First, the method of preparation as described by Czerny and Kleinschmidt is unnecessary according to the results obtained in the cases which provide the basis of this study, as in no instance was this method followed. Second, while admirable results were obtained by the simple addition of boiled butter to a suitable dilution of skim milk there is an important practical objection to its use in this manner by reason of the fact that boiled butter will not readily emulsify in such a mixture and rises to the surface. Thus, if the infant should happen not to finish its bottle this portion of the ration will be lost. While this difficulty may be partially overcome by thoroughly whipping the mixture with an egg beater and by frequent agitation of the bottle during the act of feeding, nevertheless the addition of starch in some form, either as a cereal decoction or as the pulverized flour ball, will insure a more thorough distribution of the butter throughout the mixture. For practical purposes one half to one ounce by measure of the flour ball will be sufficient for a twenty ounce mixture. It cannot be too strongly emphasized, however, that experience seems to prove that there is no need for the starch addition to insure the digestion of the butter. A paste is made of the flour ball and two or three ounces of the skim milk mixture. The remaining portion of the mixture is made hot in a double boiler and then thoroughly mixed with the paste and the whole boiled two minutes, whipped till cool, and then bottled. The fat will rise to the top of each bottle but when the latter is warmed and shaken preparatory to feeding the fat is found to be well distributed throughout the mixture.

---

[1] Since writing this article my experience now includes some one hundred and ten cases and there seems to be no good reason to depart from the conclusions enumerated.

The preparation of the butter itself is not difficult. It need not be freshly prepared each day. One quarter of a pound or more of sweet butter is melted in a deep agate cup. It is then slowly boiled over a low flame from three to five minutes. The time is not counted until the butter actually boils. It is then kept in agate or china on ice. The finished product neither tastes nor smells like butter. As stated the presence of small carbon particles may be disregarded.

The fatty acids contained in bovine butter fat have long been recognized to exist in a much less stable combination than those found in human milk, and in order to determine whether the tolerability for boiled butter depended upon the complete or partial dissipation of these acids by reason of the high degree of temperature to which they were subjected, the following experiment was undertaken, at my suggestion, by Dr. A. I. Rubenstone, of the Mt. Sinai Hospital.

1. a. One hundred c. c. of melted sweet butter, unboiled, bought in the open market, were tested for total acidity in terms of decinormal sodium hydroxide and it was found that twenty-seven c. c. of this solution were necessary to accomplish neutralization. b. After boiling one hundred c. c. of sweet butter slowly for five minutes it was found that eleven c. c. of the decinormal sodium hydroxide solution were necessary to accomplish neutralization.

2. a. One hundred c. c. of melted salted butter, unboiled, bought in the open market, were tested for total acidity in terms of decinormal sodium hydroxide solution and it was found that twenty-nine c. c. of this solution were necessary to accomplish neutralization. b. After boiling one hundred c. c. of salted butter slowly for five minutes it was found that fourteen c. c. of the decinormal sodium hydroxide solution were necessary to accomplish neutralization.

3. a. One hundred c. c. of cream, unboiled, bought in the open market, were tested for total acidity in terms of decinormal sodium hydroxide solution and it was found in twenty-eight c. c. of this solution were necessary to accomplish neutralization. b. After boiling one hundred c. c. of cream slowly for five minutes it was found that twenty-two c. c. of the decinormal sodium hydroxide solution were necessary to accomplish neutralization. These experiments may be briefly expressed as follows:

A. 1. 100 c. c. raw melted sweet butter plus 27 c. c. N/10 Na OH solution=neutrality.
2. 100 c. c. sweet butter boiled five minutes plus 11 c. c. N/10 Na OH solution=neutrality.
B. 1. 100 c. c. raw salted butter plus 29 c. c. N/10 Na OH solution=neutrality.
2. 100 c. c. salted butter boiled five minutes plus 14 c. c. N/10 Na OH solution=neutrality.
C. 1. 100 c. c. raw cream plus 28 c. c. N/10 Na OH solution=neutrality.
2. 100 c. c. cream boiled five minutes plus 22 c. c. N/10 Na OH solution=neutrality.

It appears that the total acidity of salt butter is slightly in excess of that of sweet butter and that of cream corresponds about to that of salted butter. Further, it is noted that boiling reduces the total acidity of both sweet and salted butter by a little more than half and that this is most pronounced in the case of sweet butter. The most striking feature, however, of this experiment is that comparing the effect of boiling upon both sweet and salted butter with that upon cream it is noted that there is comparatively little effect from boiling upon the latter. By this simple investigation it appears, therefore, that an explanation is available as to why cream, when added boiled or unboiled to milk formulas, frequently causes acute alimentary disturbance as manifested by vomiting, diarrhea and loss of weight. On the other hand, it appears patent as to why the addition of either boiled sweet or salted butter is without this effect and the preference seems to point toward sweet butter although clinically no difference in effect has been experienced. Mere boiling of milk and cream mixtures does not assist in the digestion of fat, although it does improve the digestibility of the curd.

It was noted while boiling butter that, without decreasing the degree of heat which is necessary originally to cause boiling, ebullition would cease and from thence onward charring or carbonization occurred, the effect of which was to cause the formation of a brownish or black sediment. It was therefore determined to ascertain what relationship existed between the duration of the boiling and the reduction of the acidity. With this in view Dr. A. I. Rubenstone, at my suggestion, kindly carried out the following experiment, the numerals expressing the number of cubic centimetres of decinormal sodium hydroxide solution necessary to bring about neutrality.

Sweet butter: Before boiling, 26.4 c. c.; boiled one minute, 17.2 c. c.; boiled two minutes, 14 c. c.; boiled three to four minutes, 13.8 c. c.; boiled five minutes, 13.5 c. c. These figures are averages obtained from repeating the operation four times.

It will be noted that practically the same degree of reduction is obtained from boiling the butter two minutes as from the longer periods. Clinically, however, it has been determined that better results are obtained when the boiling is prolonged a little longer —preferably to four minutes—and a slight degree of carbonization appears to be advantageous. It is extremely important that the directions as to boiling be explicitly given and carefully carried out, stress being placed upon the fact that four minutes means actual boiling. It is also essential to impress upon the mother that the milk employed in the mixture must be thoroughly and carefully skimmed else the purpose for which the boiled butter is substituted for the cream will be defeated and the results will not be so good.

The well known growth producing qualities of the fat soluble A vitamine and its presence in butter fat suggested the thought that it may, in raw butter and in cream, be inhibited in its functional activity by reason of the close proximity of an excess of volatile fatty acids and that by reason of their destruction or diminution in boiled butter this activity may be released to functionate to its fullest extent. There is as yet no scientific proof of this, inasmuch as the heat necessary to boil the butter may at the same time inactivate the fat soluble A vitamine. However, the gain in weight in many instances was so great and so instantaneous and entirely out of proportion to the amount of nourishment given that it appeared that nothing short of a tremendous impetus to growth had been provided by an unrecognized factor. At the present time I am conducting animal experiments in this connection and hope to report my results at a later date.

CONCLUSIONS.

1. Volatile fatty acids exist in butter in even less stable combination than they do in cream.
2. Boiling butter five minutes slowly will drive off over fifty per cent. of these acids.
3. Boiling butter two minutes is sufficient for clinical purposes; however, from three to four minutes would probably be a safer average.
4. Sweet butter contains less volatile fatty acids than does salted butter.
5. Boiling cream does not materially change its acid content.
6. Boiled butter may be added advantageously, in varying and gradually increasing quantities, to skim milk formulas or other food combinations.
7. Boiled butter appears to be a more acceptable addition to milk formulas than does cream.
8. The presence of flour or other forms of starch, though acceptable, to ensure an even distribution of the fat, are not necessary essentials to the digestibility of boiled butter; especially they do not have to be present in equal amounts.
9. Vomiting and diarrhea are neither inaugurated nor made worse by the addition of boiled butter; on the contrary, they often cease after the addition of this substance.
10. Constipation has been the rule and the reaction of the stool has been found to be feebly or markedly alkaline.
11. All cases, free of parenteral disturbances, to which this substance has been fed, have experienced a uniform gain in weight, averaging on ounce to nearly two ounces per diem.

2011 Chestnut Street.

Blood Transfusion in Malnutrition and Infantile Atrophy*

By J. D. LEEBRON, M.D.,
Philadelphia,

Instructor in Pediatrics, Graduate School of Medicine, University of Pennsylvania, Chief of the Pediatric Clinic and Visiting Physician to the Children's Ward of the Polyclinic Hospital.

In presenting this report it is not my intention to affirm that transfusion is a definite therapeutic agent or a cureall in such cases. In all cases of malnutrition and infantile atrophy that either do not respond to tried measures or fail to make any progress, transfusion, if properly carried out, is practically devoid of danger and is the means of bringing an early favorable outcome. In this series of cases in which we have used transfusions and in such athreptic cases where we intend to use it in the future, all conservative pediatric measures have been and will be carried out before transfusion is considered.

INDICATIONS.

The indications for transfusion in malnutrition and infantile atrophy, as we consider them, are: 1, improper assimilation of food resulting in atrophy and progressive loss of weight; 2, secondary anemias from any cause resulting in malnutrition; 3, circulatory depletion from such conditions as acute gastrointestinal disturbances with the associated signs of collapse; 4, those cases of apparent exhaustion in which we find cold extremities, a semicyanosis of the skin, very feeble heart sounds and a thready pulse, and where a definite diagnosis cannot be established.

AMOUNT OF BLOOD.

This is one of the most important factors for success in the transfusion of infants. Many failures and deaths are no doubt due to hypertransfusion. It is better to give small amounts, repeated in ten days or two weeks, than to give a large amount at the first operation. Lucas and Dearing (1) have pointed out the variability of blood volume in infants. They report the average blood volume as 147 c. c. to the kilogram of body weight (4.7 per cent.). We have felt that we were within the limits of safety by transfusing 10 c. c. to the pound of body weight. With this rule as our criterion we have never had any of our patients exhibit symptoms of an overdose which are those of over distention of the right ventricle.

---

*Read before the Northern Medical Association January 13, 1923.

DONORS.

In choosing donors for transfusion of infants three things are necessary; first, a negative Wassermann reaction; second, a blood count, and third, a careful estimate of the compatibility of the donor's and recipient's blood. In an emergency the first two may be omitted but under no circumstances the last. Although Kimpton states that children under two years of age probably belong to no group, Pemberton, from the Mayo clinic, states that infants develop their own group after the first two weeks. Cherry and Langrock (2), in a series of thirty-four cases, used the mothers as the donors for transfusion in newly born infants with no untoward results. In those cases in which the patient is extremely ill, or in which the type reading is at all doubtful, a crossed hemolysis test should be made.

METHOD.

There is a great difference of opinion as to which method should be used for transfusion. Three of the children in our series were transfused by the citrate method and two by the socalled direct method, the syringe cannula being used. It is unnecessary in this paper to discuss the collection of the blood from the donor. The infant is wrapped in a sheet, with the head exposed and placed flat on its back. It is of the utmost importance to have an assistant who understands what you are attempting to do, as this results in cooperation avoiding friction and loss of time. If the anterior fontanelle is still open, the superior longitudinal sinus route is employed. The hair is shaved from the anterior fontanelle and a five per cent. solution of picric acid in alcohol is applied for skin sterilization. The fontanelle is then divided into four equal parts, and a needle of fairly large caliber, about an eighteen gauge, is inserted at the anterior internal angle of the right posterior quadrant. As soon as the blood begins to flow from the needle, the syringe or the adapter from the citrate cannula is attached and the flow established. After the administration of the first five or ten c. c. we wait a few minutes to see if there has been any slip in our typing technic. If no reaction is visible, the transfusion is continued.

It is important to administer the blood very slowly. We allow forty to sixty seconds for each c. c. of blood to enter. There is no doubt in our minds that in some of the cases of reported fatalities the cause of death has been a too rapid introduction of the transfused blood. In cases where it is impossible to use the superior longitudinal sinus the median bacilic or cephalic vein may be used, and if these are too small, an attempt can be made to utilize the internal saphenous vein at the knee.

In our series of cases we had one severe reaction which lasted twenty-four hours. This followed a second transfusion. The child had been removed to another hospital for the operation, and it is possible that the moving of the very sick infant backward and forward may have played some part. However, the child afterwards improved and made a very excellent recovery. Meleny has shown (3) the more transfusions a patient is given the more likely he is to have a reaction.

The transfusion of dehydrated cases seems to replenish the depleted circulation in a more stable manner than the intraperitoneal saline injections. This may be due to the fact that saline infusion does not maintain the blood volume as long as does blood. The blood probably helps in two ways. Ashby (4) of the Mayo clinic has shown that the red blood corpuscles remain as functionating cells in the circulation for about thirty days. In summing up her article she says: "The beneficial results of transfusion are without doubt not due primarily to a stimulating effect on the bone marrow, but, it is reasonable to assume, to the functioning of the transfused corpuscles." This is not agreed to by all observers and we agree with Stengel that in the anemias hematopoietic function is stimulated by the transfusion. In all our cases the patients showed a general improvement in health with a disappearance of the restlessness and anuria and an improvement in the general nutrition. The hemoglobin increased from ten per cent. to twenty per cent. with each transfusion, and the red blood cells increased as high as two million.

Robertson, Brown and Simpson (5) have shown that in eighty-seven cases of marasmus, in which transfusion was done, the mortality was forty-five per cent., while in another series of cases, which was managed with and without transfusions, the mortality was fifty-seven per cent. In the first series twenty-one per cent. of the patients were in a state of collapse at the time of transfusion. Their average weight at five months was seven pounds. Of the collapsed patients forty-three per cent. made a complete recovery. In the second series eighty-two per cent. of the moribund patients died. The average red count before transfusion was a million and a half red blood cells, sixty per cent. hemoglobin. This was raised to an average of five million reds and eighty per cent. hemoglobin. It will thus be seen that in most of the cases there was a moderate degree of secondary anemia. The patients having no anemia benefited little from the transfusion. In the majority of cases there was no immediate change in the weight, but there was a definite improvement, as was manifested by tolerance to food, and a lessened tendency to a subnormal temperature. In some cases there was an immediate gain in weight, and the injection of blood was a big factor in life saving. We agree with the authors that any remedy that reduces a mortality from fifty-seven per cent. to forty-five per cent. and in the moribund cases from eighty-two per cent. to forty-three per cent. is worthy of serious consideration.

CONCLUSION.

1. The transfusion of blood by any method is a simple and often a life saving procedure.
2. We have found it of distinct value in the treatment of cases of malnutrition and infantile atrophy.
3. It is of the utmost importance to be careful in the amount of blood transfused and in the rapidity of its introduction.
4. The route for introduction in infants seems to be simplest if the superior longitudinal sinus is used.

I am indebted to Dr. Ravdin for his valuable assistance and cooperation in this preliminary report. I feel certain that the success in this short series of cases was entirely due to his fine technic and the careful manner in which he performed transfusion.

THE DISCOVERY OF VACCINATION

Edward Jenner, the discoverer of vaccination, died in the same village in which he was born, Berkeley, Gloucestershire, England, on January 26, 1823. The principle of immunization against smallpox had been known for a considerable time and was introduced into England by the celebrated, in some ways notorious, Lady Mary Montague, who had observed in Constantinople that by its employment a certain amount of protection was afforded against smallpox. Somewhat later, inoculation against variola was introduced into New England. As a matter of fact Jenner then applied in his own practice a variation of a method which had been proved of value in modifying the severity of an attack of smallpox. At the same time he was truly the discoverer of scientific vaccination and thereby one of the greatest benefactors to the human race who ever lived.

There is no need to go over the history of Jenner's discovery. It is enough to say that living in a part of the country in which dairy farming was largely carried on, he was aware of the popular belief that cowpox, when introduced in the human system, prevented smallpox or greatly modified the acuteness of an attack.

In 1796, twenty-one years after he had begun to make experiments and to investigate the matter, he performed his first public vaccination, having previously inoculated his own son, aged one and a half years, with cowpox. The lymph for the vaccination came from the hand of a dairy maid infected in the course of her work. The vaccination was successful and from that time on Jenner practised regularly his new method. In 1798 he published his famous *Inquiry Into the Causes and Effects of the Variolæ Vaccinæ,* a disease discovered in the Western counties of England, particularly Gloucestershire, and known by the name of cowpox. It was not long before vaccination was being practised in every country of the globe and Jenner received honors from a world much more cognizant of the terrors of smallpox than the present world. Also Jenner was a prophet not without honor in his own country, for a grant from the British Parliament of £10,000 was made to him. Jenner may be aptly termed the father of preventive medicine, while Pasteur, if he did not quite place the coping stone on it, at least carried on and raised the work begun by Jenner to an unprecedented height.

It has been proved times without number and up to the hilt, that vaccination is a great preventive of smallpox. If it does not stamp out the disease its type in countries in which vaccination has been practised is of far less virulence. But a generation has arisen which knew not smallpox as it exhibited itself in the time of Jenner. It was the greatest menace from the disease viewpoint that then existed, and the discovery of the country practitioner of Gloucestershire relieved the minds of the community at large of a dread which like the sword of Damocles was continually hanging over them, a dread which may be compared to a lesser extent to that of cancer in the present day.

No doubt the disregard with which vaccination is now regarded is due to the indifference to smallpox engendered by the fact that little of the disease is seen and when seen is of a mild type. But it is well to point out that there may be a rude awakening from this fool's paradise. Virulent smallpox still exists in certain parts of the world, and if imported into an area inhabited by unvaccinated persons might quickly work dire havoc. A warning of this kind was afforded a short time ago in a riverside district of London, the population of which were largely unvaccinated. Smallpox of a severe type was introduced from the near or far East, in which as an aftermath of the war virulent epidemics are now raging, and the result was that several deaths occurred. This warning was not without its advantages, as there was a rush to be vaccinated. It is feared that the spasm of common sense will, like all such spasms, only last for a short time, and will need another sharp lesson to bring about a recurrence of common sense.

The public may be reminded that vaccination against smallpox, since the introduction of glycerinated vaccine by Dr. Monckton Copeman, is entirely free from danger and thereby it is a bounden duty laid upon the individual that he should protect himself from infection whenever possible, so as not to be a source of danger to his fellow creatures. The life of Edward Jenner and the history of vaccination may be recommended as instructive reading and should dispel ignorance and point a moral.

THE HEART AND RESPIRATORY SYSTEM IN SCARLET FEVER

Although there is little to add to the classical description of endocarditis and pericarditis complicating scarlet fever, that of myocarditis and cardiovascular disturbances has been of late considerably enriched. Scarlatinal endocarditis is rare—according to Broadbent's statistics of 1907 it occurred only in

0.58 per cent. of the cases. It occurs with or without rheumatism, is usually mild but frequently gives rise to a chronic valvular lesion. It can be easily overlooked as the functional symptoms to which it gives rise are usually unimportant. Septic ulcerating endocarditis is rare and usually ends in death. Pericarditis may exist alone or be associated with dry serofibrinous or purulent endocarditis; it is likely to be latent and rapidly retrogresses, but if purulent, death is prone to occur.

As to the functional disturbances of the myocardium there is usually tachycardia at the outset and the older writers insisted upon this symptom as a good diagnostic sign of scarlet fever. The pulse rate varies from one minute to another and there is marked arterial hypotension as well. But instead of tachycardia there may be a relative or absolute bradycardia, although in children this is not frequent. Bradycardia is met with rather constantly at the end of the phase of pyrexia, taking the place of the tachycardia. It lasts for eighteen to twenty days and is of nervous origin, total and without auriculoventricular dissociation. Various types of arrhythmia as well as other changes in the pulse are encountered.

The blood pressure is low in the malignant syndrome of the disease in question and adrenalin exercises a favorable influence. On the other hand, there is hypertension with the acute nephritis of scarlet fever which retrogresses slowly, even when the other symptoms of the renal process have disappeared.

There exist two syndromes which, for that matter, may be combined: First, the myocarditic syndrome which does not always depend upon lesions of the myocardium, being often due to extracardiac causes, especially changes arising in the suprarenals, and secondly, cardiac disturbances due to nephritis. These are often early in appearance and predominating so that the patient seems to be a cardiac rather than a renal subject, presenting edema, enlarged liver, scanty albuminous urine, a small frequent and irregular pulse and an enlarged heart with a *bruit de galop*. In the subacute types all these symptoms are attenuated but become intense if the nephritis becomes chronic.

The complications arising in the respiratory tract in scarlet fever, other than purulent rhinitis, pleurisy and empyema, are hardly mentioned in textbooks. Cases of serious pseudocroup due to the streptococcus have been recorded, intubation being rendered difficult on account of spasm while a reflex may start from the irritated larynx inhibiting the cardiac contractions, hence syncope, sometimes ending in death.

Bronchopneumonia is not uncommon in the more serious cases of the disease while instances of lobar pneumonia have likewise been met with. The predilection of scarlet fever for the serous membranes and fibrous tissue has long been known, hence pleural collections develop in the rheumatic ural processes of the affection with or without endopericarditis. A streptococcal or pneumococcal pleurisy is also known to occur. Finally as an intercurrent complication acute pulmonary tuberculosis or tuberculous pleurisy may ensue, but scarlet fever is not a tuberculigenous disease, therefore these complications are uncommon.

PSYCHIATRY AND DELINQUENCY

"What have psychiatry and psychology to offer as aids in the field of delinquency?" asks Dr. Bernard Glueck in a very interesting and illuminating article on The Psychiatric Attitude in a recent number of the *Survey*. He goes on to say: "If by the field of delinquency is meant the traditional enterprise for the administration of the law, I am afraid these sciences can be of very little aid. Psychology, as the science of the mind and human behavior, and psychiatry, which literally means mindhealing, are tools for different purposes than those reflected in the processes of the criminal law. If we are honest with ourselves, we must say that these processes have refused in the past to have anything to do with questions of understanding and healing. The criminal problem is not kept alive by the occasional offence of a first offender but by an ever increasing element in our population who seem to have accepted criminal behavior as a life career. It is these individuals who may have had repeated contact with the established machinery of the law who attest to the utter failure of these processes to affect materially the problem of crime. But if by the field of delinquency we mean those social service enterprises which have been made possible in spite of certain aspects of criminal procedure, these sciences of human behavior can make themselves felt very decidedly in connection with the administration of the problem of crime. Delinquency, when viewed in an impartial and unbiased fashion, is quite understandable as a problem in human behavior. As such, the workers in this field can at once avail themselves of a fairly well organized and dependable technic for the understanding and direction of human behavior."

Doctor Glueck proceeds to describe in brief this technic. Perhaps the most important element is the psychological and psychiatric attitude toward a problem. Only the inexperienced physician or social worker ever indulges in the holier than thou attitude. Intimate contact with the problems of life and increasing selfknowledge are bound to remove the obstacles to cultivating a proper conception of the understanding and service involved. Another thing to be cultivated is the scientific conviction that "nothing in human behavior happens quite fortuitously and out of a clear sky; that the only way in which one can discover and evaluate causes is to approach a question free from preconceptions." A delinquent act has usually multiple causes. Psychology and psychiatry, more than any other approach to the problem, aim to base conclusions upon an evaluation of all the biological, psychological, social, economic and pathological factors in the case.

Another question as to proper attitude concerns the scope of psychiatry. Once, and sometimes now, the function of this science, in regard to criminology was limited to a statement as to whether or not the delinquent was feebleminded or insane—in other words, was he responsible for his crime? "Now, in actual practice, psychiatry has come to define its task to be that of understanding and treatment of human behavior. The issues of disease or defectiveness are only some of the issues it meets, and as soon as such issues become established in connection with a problem of delinquency, they become problems in medicine and should be dealt with mainly, if not exclusively, from a medical standpoint."

The true scope of psychiatry, then, is to be found in the kinds of facts it deals with. These are, the writer goes on to say, first, the elements of human nature relating to man's inherited dispositions to action and reflecting the history of his descent—in other words, his "biologic destiny"; second, the "acquired or learned equipment of man," enabling him to act and adapt himself of the conditions of life automatically or reflexly. The nature of this acquired equipment is determined, indirectly at least, by innate dispositions, leading their possessor to shun or to seek out certain life experiences. The psychiatrist must recognize the close and important relationship of these factors. "Without such a conception, it would be difficult to account for the real differences in traits and life pursuits between races and peoples, as well as between certain pathologically disposed individuals, like the true epileptic, for instance, and the normal human being."

The next subject with which psychiatry concerns itself is the true evaluation of those circumstances of life common to all individuals, such as the problem of emancipation from the home, of proper self esteem, of sex, and of various other critical times in the life and development of every person, requiring more than the usual adaptive capacity, such as the acute periods of puberty and adolescence, of aging and decline, of grief and bereavement. Psychiatry must study also the actual failures in adjustment and the definite factors involved, such as heredity, injury, infection, exhaustion, emotional insults, bad habits, and other conditions.

"Finally, psychiatry is concerned with the technic of human readjustment and with those positive principles of a hygiene of the mind that might be utilized as preventives of failures in human adaptation and as means towards a more effective conscious control of the human machine. . . . If psychiatry is not making itself more effective in connection with the problem of crime, it is due both to limited opportunity and imperfect technic. But it knows its objectives, and it is up to those who believe in the introduction of a social service point of view into the field of delinquency to see to it that this point of view embraces the aims and technic of psychiatry."

DEATHS FOLLOWING OPERATIONS ON THE NOSE AND THROAT NOT DEPENDENT UPON ANESTHESIA.

We have long been accustomed to attach the minimum danger of death to operations on the throat and nose. Of course we are well aware that the most trivial operation on the human body may be followed by the death of the patient. The doctor may inadvertently operate on a bleeder, the anesthetic may kill the patient, or an intercurrent disease, independent of the operation, may prove fatal, so when a patient dies after such an operation we feel sorry for the doctor, but are not much impressed. But our attention is arrested when Hanau W. Loeb gives us (*Annals of Otology, Rhinology and Laryngology, June*, 1922,) the records of 332 such deaths, and the way in which he collated them. He found the literature on the subject very meagre, so he sent a questionnaire to five thousand physicians who, according to the *American Medical Directory*, profess to be qualified to practise the specialty of nose and throat diseases. Only seven hundred, fourteen per cent., replied, the remainder ignoring his request for information. But this fourteen per cent. furnished him a number which, when added to the few cases in literature and a case of his own, gave a total of 332 deaths, not dependent on anesthesia, which have followed operations of this nature. What the total would have been had the eighty-six per cent. replied must remain a matter of conjecture, but perhaps we are justified in one inference. While it is probable that many of the five thousand listed as specialists are not well trained, mentally alert and conscientious, past experience has shown that those most ready to furnish data concerning their misfortunes are those who qualify best, and among whom the number of fatalities would be least.

An analysis of these 332 fatalities is interesting. The causes of death were: meningitis in 125 cases; hemorrhage in fifty-five; general sepsis in twenty; erysipelas in eight; affections of the endocranium (excluding meningitis) in twenty-six; of the respiratory tract in forty-three; of the heart in five; miscellaneous, twenty; undetermined, thirty.

Meningitis proved fatal in five cases after removal of adenoids and tonsils. In one, the disease was probably present when the operation was performed, in two its onset may have been due to an intervening acute suppurative otitis media, but in two the causal relation could not be explained so readily. The other operations followed by a fatal meningitis were: Intranasal frontal, sixteen; probing and irrigating frontal sinus, seven; ethmoid, with or without resection of middle turbinate, thirty-nine; sphenoid, ten; maxillary, one; resection of middle turbinate, fifteen; submucous resection of the septum, thirteen; removal of polypi, thirteen; combined sinus operation, one; combined submucous and sinus operation, five. In most instances meningeal symptoms appeared within forty-eight hours after the operation.

Death from hemorrhage followed tonsillectomy, with or without adenoidectomy, in forty-three cases; adenoidectomy alone in two; incision of peritonsillar abscess in three; submucous resection in two; sinus operation in four; resection of the inferior turbinate in one. General sepsis was responsible for death after two intranasal maxillary operations, one submucous resection, sixteen tonsillectomies, and one incision of peritonsillar abscess; erysipelas after four submucous resections, two sinus operations, and two resections of the middle turbinate.

Death was ascribed in five cases to brain abscess, in nine to cavernous sinus thrombosis, in twelve to cerebral embolus or hemorrhage, but in only a few of these was the diagnosis confirmed by autopsy. Most of the remaining causes of death tend to give one the impression that the operations were performed on persons unsuited to operation at all and suggest lack of judgment on the part of the operator, but the cause of death was not determined after the following: Tonsillectomy, sixteen; adenoidectomy alone, one; exenteration of the ethmoid, four; puncture of nasomaxillary wall and irrigation of sinus, five; submucous resection, one; resection of middle turbinate, two; combined tonsillectomy and submucous resection, one.

Such a list of fatalities after operations which are commonly considered almost devoid of danger is, to say the least, striking. The mortality risk cannot be great in percentage, but evidently it is considerably greater than it is usually supposed to be. We wish we had space to reprint the reflections with which Loeb closes his paper. The best we can do is to quote a few and urge their careful consideration by anyone and everyone who contemplates performing an operation of this nature.

Knowledge of the anatomy of the nose and throat cannot be learned by operating on the living patient, yet how many try to acquire it by surgery rather than by arduous study in the dissecting room. To operate without this knowledge is impossible for a man of conscience, not to mention the hazard to the patient. The patient himself, not the disease or its name, should be studied to determine whether he is a proper subject for operation and will be benefitted by it. When possible, the operation should be performed in a hospital. Rigid attention to asepsis is essential, not by washing the field with antiseptic solutions or by applying iodine, but by operating with an aseptic organization such as would be used in any other important surgical operation. It is better to take out too little than too much, even if a second operation may be required. Multiple unrelated operations are an abomination. To operate and then to consign the patient to inexpert hands can have no justification. A better surgeon is required to supervise the aftertreatment than to perform the operation.

CHANGES IN METHODS OF TREATMENT

In order to treat a patient with any hope of success, an accurate diagnosis must be made, that is to say, a diagnosis of the underlying cause or causes. If a cure is to be anticipated the treatment of symptoms, while necessary for relief, is comparatively futile. Of course, the ideal mode of treatment is that advocated by Sir James Mackenzie, the preventive treatment par excellence, to diagnose and treat the beginnings of disease, and to nip it in the bud. However, at present, such a course is impossible on a large scale. Not only must medical practitioners generally be educated to diagnose with at least approximate correctness the beginnings of disease, but the public must be educated to consult the medical man for slight ailments. The average individual is averse from doing so. As a rule, he does not call in the doctor until he feels really sick, except when attacked by an acute complaint. Consequently, in the majority of cases the disease has made considerable headway, ere the advice and aid of the physician is invoked, and the problem then is to discover the *causa causans*.

Many of the medical students of the present day do not rise above symptomatic treatment and do not attempt to probe deeper and try to discover the primary origin of any obvious malady. The argument is not advanced that the newly graduated practitioner is not well equipped with medical or surgical knowledge as far as it goes, and the same may be said with regard to therapeutics. He has learned to diagnose the more common affections, as well as the more important of the grave diseases and injuries, and his hospital training has taught him the routine treatment of such. But, as said before, he has not been taught and has not had the opportunity to observe the early manifestations of many serious sicknesses, for the simple reason that persons seldom ask medical or hospital advice for what they consider trivial complaints. In a hospital, routine treatment is usually followed, and the student is not instructed to look for in apparently similar cases a different underlying cause or other causes, and vary therapeutic treatment accordingly, and the reasons for this deviation from accepted methods. If he should be ambitious and keenly intelligent, he will make it his business to learn this aspect of treatment from personal experience, will endeavor to find out the obscure cause or causes, and will found his treatment, therapeutic and otherwise, on the results of his investigation.

Little help in this direction is given by teachers on textbooks except that the cause should always be treated, and it frequently happens that this excellent advice is impossible to follow because the cause cannot be discovered. It may be pointed out that even when the origin of a grave condition is wrapped in obscurity that more can be done in the way of preventing its further progress than is generally conceded, although ignorance of the early cause or causes may exist.

Perhaps there is no more fruitful cause of disease than habitual constipation, in fact it may be stated without incurring the stigma of employing exaggerated language that chronic constipation leading to chronic intestinal stasis is the cause of more fatal diseases than any other one cause. And yet how easy to prevent it in perhaps the majority of cases in its early stages. Cancer usually can be greatly relieved if not cured if taken in time. In any event, life can be prolonged considerably and much suffering avoided if a medical man is consulted and steps are taken when the early manifestations of the disease are observed. The same may be said of a long list of diseases, and the point requires no further elaboration.

Early and accurate diagnosis and early and effective treatment should be the slogans of the medical profession. By these means disease will be largely prevented. But, as it is utopian at present to hope for such an outcome, progress must be steadily made along the path referred to above. The changes made and being made in the practice of medicine are based on sound common sense.

In conclusion, attention may be drawn to the increasing interest now evinced by medical men in the influence of mind over bodily afflictions. It is recognized that the mind is capable of treatment to an extent which it would not have been believed to be capable of but a few years ago.

THE PHYSICIAN'S BEDSIDE MANNER.

A good bedside manner is an extremely valuable asset to the physician, indeed it may even make or mar the fortune of a young medical man. Only a genius or an exceptionally able man can afford to be eccentric; for the man of ordinary ability "dress and address" are strong points in his favor. Some physicians have relied almost wholly for success on a good appearance with suave and pleasing manners, and it may be said with most satisfactory results as far as material prosperity is concerned. The aim of the physician is to gain the confidence of his patient. When this has been accomplished he has made a long step in the direction of restoring the patient to health, that is, when no organic disease exists, and even when such is the case, confidence in the medical attendant is of great value.

It is true that many doctors have made fortunes by their charming bedside manners. Sir Richard Quain used to tell how, when quite a young man, he was called in to assist a well known physician of today. The young man assumed an expression which he thought correct, but which did not impress his senior in the same way, who remarked, "for heaven's sake man don't look like that or they will think you are the undertaker." On another occasion it is related that a doctor after dining not wisely but too well was called hurriedly to the bedside of a certain wealthy society woman. He arrived at the house although considerably bemused, and his first act was to take his watch from his vest pocket to count her pulse. This, however, in his befuddled condition was too much for him and proceeding to replace it he muttered to himself "drunk again." To his astonishment the lady caught hold of his hand and with tears cried out, "Yes I know, but oh doctor, don't mention it and it shall never occur again."

But this is somewhat of a digression from the theme of this editorial, which is to emphasize the value of a good bedside manner. The successful practitioner of the present day, whether specialist or general practitioner, should be something of a psychologist. While manners certainly go a long way with the sick, the personal equation should always be considered. A sick person is sensitive to outward impressions, and while a breezy genial manner may reassure some patients it by no means appeals to all patients. Therefore the doctor should be a psychologist and regulate his manners to accord with the conditions he is called upon to meet. It goes without saying, also, that in order to do the greatest amount of good pleasing manners should be supplemented by knowledge, experience and skill. However, good manners are a desirable asset to the physician in any event and are to some extent within the reach of all.

A CORRECTION

Through an error, Pasteur's photograph appeared in place of that of Weismann in Dr. J. Arthur Buchanan's article on Theories and Theorizers Connected with the Development of the Laws of Heredity, in the preceding issue of the New York Medical Journal and Medical Record. We regret that this occurred. In the reprint of Dr. Buchanan's splendid article the correction will be made and the references in his article will also be included.

News Items.

Medical Society of the County of Erie.—There will be a special meeting of the Medical Society of the County of Erie to discuss the Workman's Compensation Law, Monday evening, March 5, 1923.

Wyeth Memorial Meeting.—A memorial meeting to the late Dr. John Allan Wyeth was held on Tuesday, February 27th, 4:30 p. m., at the New York Polyclinic Medical School and Hospital, 349 West Fiftieth Street. Following the memorial service the building was formally opened for inspection.

Eighth Harvey Lecture.—Dr. E. V. Cowdry, of the Rockefeller Institute for Medical Research, will deliver the eighth Harvey Society Lecture at the New York Academy of Medicine on Saturday evening, March 10, 1923. His subject will be The Significance of the Internal Reticular Apparatus of Golgi in Cellular Physiology.

Rockefeller Foundation Election.—The Rockefeller Foundation has elected to its board of trustees Dr. Ray Lyman Wilbur, president of Stanford University, California, and William Allen White, writer and newspaper editor, of Emporia, Kan.; and to membership on its International Health Board, Dr. David L. Edsall, Dean of the Harvard Medical School.

New York Doctor Opens Discussion.—Dr. Leo L. Michel, of New York City, opened the discussion on the paper by Sir John Thomson Walker, F. R. C. S., entitled Obscure Symptoms Caused by Pyelitis, before the British Medical Association, February 8th. He sailed for home February 24, 1923, after an intensive study of European clinics on genitourinary diseases and rejuvenation.

Annual Meeting of the Eyesight Conservation Council.—The annual meeting and election of the Eyesight Conservation Council of America was held in New York on Tuesday, February 6, 1923, at the Pennsylvania Hotel. President Wallace reviewed the activities of the Council during the past year. He referred to the increased interest and the gratifying response to the work, and of the encouraging outlook for 1923.

American Internal Medicine Congress.—The seventh annual clinical session of the American Congress on Internal Medicine will be held in the amphitheatres, wards, and laboratories of the various institutions concerned with medical teaching, at Philadelphia, Pa., beginning Monday, April 2, 1923.

Practitioners and laboratory workers interested in the progress of scientific, clinical, and research medicine are invited to take advantage of the opportunities afforded by this session.

Lincoln Memorial University Confers Degrees.—At the semiannual meeting of the board of trustees of the Lincoln Memorial University, held in Washington on Lincoln's Birthday, the honorary degree of Doctor of Science was conferred upon Dr. Eugene Hertoghe, of Antwerp, Belgium. At this same time Dr. William Seaman Bainbridge, of New York, received the honorary degree of Doctor of Letters, and Secretary of War Weeks, Secretary of the Navy Mellon, and Dr. John Harvey Kellogg, of Battle Creek, the honorary degree of Doctor of Laws.

Women's Medical Society Meeting. — The Women's Medical Society of New York State will hold its annual meeting 9:30 a. m., May 21, 1923, in New York City. All medical women, members, nonmembers, and their friends are cordially invited to attend both the scientific session and the banquet.

Columbia Appoints Two British Lecturers.—Appointments of British scholars to lectureships in the Law School were announced by the trustees of Columbia University. William Renwick Riddell, Justice of the Supreme Court of Ontario, was named Blumenthal Lecturer for the spring session. Sir Paul Vinogradof, Corpus Professor of Jurisprudence at Oxford University, will be Carpentier Lecturer for 1923-24.

College for Rehabilitation.—At a meeting held at the Academy of Medicine of New York, a company was incorporated for the establishment of an American College of Rehabilitation for training workers in the field of reconstruction of the wounded and crippled. Major Franklin W. Johnson, of Columbia University, described the rehabilitation work carried on during and after the war among disabled soldiers. The work is a combination of surgical and social. Its sponsors are Dr. Fred. H. Albee, Mrs. Clarence Cary, Martin A. Metzner, W. J. Hoggson, R. Gradwell, and Standish Chard.

David E. Hoag Reappointed.—Dr. David E. Hoag, who was commissioned as captain in the Medical Corps, United States Army, in the World War, and who was honorably discharged, has been reappointed by the President, through the Adjutant General of the War Department, as Captain in the Medical Reserve Corps, Second Corps Area, Seventy-seventh Division, United States Army. Dr. Hoag is lecturer in the department of nervous and mental diseases in the New York University and Bellevue Hospital Medical College, associate neurologist at the Post Graduate Hospital, and associate visiting physician to the New York Polyclinic Hospital.

Radiological Award.—The Radiological Society of North America has awarded its gold medal "for distinguished services to the science of radiology" to Dr. Percy Brown, a prominent physician of Boston for the last twenty years, now an associate of the Jackson Clinic at Madison, Wis. The presentation was made at a meeting of the society at Detroit. The society's medal was awarded on the same occasion to Dr. Marie Curie, discoverer of radium, and to Dr. Maud Slye, of Chicago, and Dr. Gosta Forssell, of Stockholm, distinguished scientists in the field of radiology.

Reunion of the Blizzard Class.—On March 12th the Class of 1888 of Bellevue Hospital Medical College will celebrate its thirty-fifth anniversary. Because of its graduation on the day of the most terrible blizzard New York ever experienced, the class was named by the late Professor Doremus "The Blizzard Class." Dr. D. Hunter McAlpin, the class president, has invited all the surviving members to be his guests at a dinner to be given on this coming March 12th at the McAlpin Hotel. Those of the class who have not been reached by direct invitation because of faulty or insufficient address, will please communicate with the acting secretary, Dr. S. Adolphus Knopf, 16 West Ninety-fifth Street, New York City.

VIENNA LETTER.

(*From our own Correspondent.*)

Vienna, *January 11, 1923.*

INFANTILE SYPHILIS.

Dr. Bókar reports the statistics of the medical clinic of Budapest, from the years 1880 to 1915, regarding infantile syphilis. Altogether there were 174 cases of which forty-two were acquired and 132 hereditary. Of the forty-two acquired cases, the source of infection could be determined in twenty. In these forty-two cases, five patients died in the clinic, one of pneumonia, one of gastroenteritis and three of infectious diseases. Twenty-two patients lived to adult life; fifteen passed from observation. In one case the patient had tertiary symptoms at the age of eleven. The others, with the exception of occasional diseases, remained well. Of these twenty-two patients ten were men, most of them married, had families, and all the children were healthy. Of the twelve women seven are married, and four of them have no children. One of them had one child that died at the age of three years. Another had had eight children, of whom six are still alive. All the children were fairly intelligent, and showed no moral or physical defect.

In the 132 cases of hereditary syphilis, fifty-nine patients were males and seventy-three females; forty showed symptoms of the disease very early and ninety-two not until the fifth year. Of the forty cases of precocious hereditary syphilis nine patients passed from observation. Of the remaining thirty-one patients, twenty-one died in early childhood, and one at the age of eighteen of abdominal typhus. This patient was apparently quite intelligent. Of the remaining nine patients only two are still alive. One of them was morally defective and his parents were the same. The other was fairly intelligent, married, and has two living children. Of the ninety-two cases of late hereditary syphilis, eleven males died up to fifteen years of age. One of these was remarkably intelligent; some of them were morally defective. Four patients died at the ages of seventeen to twenty years. The causes of death in all cases may have been syphilis. As for the other patients, it appears that, as far as was known, they are all married and have children that are fairly healthy. Among the women there can be no doubt that there was some delay in the appearance of puberty. Of the forty-nine children born up to 1910 eight had died. There were also numerous miscarriages.

MIGRAINE PSYCHOSES.

In a recent meeting of the Vienna Neurological Society, Dr. Hirschfeld discussed the relation of migraine to epilepsy, hysteria major, and mental diseases. He said that simple hemicrania sometimes produced mental irritation or depression, anger or slight hallucinations, with migraine of an epileptic type with muscular twitchings or ocular manifestations. Can a visual aura precede an attack of migraine as well as true epilepsy? Special proof of the epileptic nature of migraine is noted when the visual aura assumes a red color. Abortive attacks can occur in both, or one be substituted for the other. Psychical symptoms or a psychical equivalent can occur in either. A transitory psychosis sometimes follows or accompanies migraine. This is important from a therapeutical viewpoint, indicating the necessity of an antiepileptic treatment for migraine.

In the same way Dr. Hirschfeld holds close clinical relations between attacks of migraine and hysteria major.

Several types of cases are met with, he said. 1. A continuation of hallucinations of sight, confusion, amnesia or ataxic aphasia, with attacks of migraine lasting several hours. 2. Confusion with religious delirium. 3. Hemicrania with temporary blindness, paresthesia of a hand, later visions of pictures, animals, and speech disturbances. 4. Hemicrania after mental shock with anxious delirium, and disturbance of consciousness for three days. The occurrence of these psychoses is, however, rare.

SMALLPOX EPIDEMIC IN BULGARIA.

Since the second half of November, last year, outbreaks of smallpox in about fifty localities in the south part of Bulgaria have ceased; and in twenty-two, or forty-four per cent. of those outbreaks the disease was restricted to the one household where the first case occurred. Notwithstanding this record of effective work by the health services, State and local, disease has continued to spread, because in the other outbreaks where the disease was not restricted to the first household, it was first called a pustulous eczema, itch, furunculosis, syphilis, impetigo, acne and not reported to the health officers so that restrictive measures could be taken. In a few instances the fault has been with the health officer himself. Because of such lack of proper reports or proper action, smallpox continued to spread. During the present epidemic the greatest number of places at which the disease was reported present, in any one week, occurred in the week ending December 23.

The Health Department of the country has sent a circular to all directors and managers of colleges, private and public schools, and convents, stating that they must insist on receiving a certificate of successful vaccination from each child before it is allowed to attend the sessions. Prompt prosecution in the recorder's court is threatened for every violation of the law.

STATUE OF PASTEUR IN BUCHAREST.

In the city of Bucharest, capital of the Roumanian Kingdom, there was recently dedicated with suitable ceremonies a statue of Pasteur, after the design of a notable sculptor. The statue is to commemorate the one hundredth anniversary of Pasteur's birth. The statue stands on the chief promenade of the city. In another Roumanian city, Oradea-Mare, a large street, leading to the hospitals and sanatoria of the city, has been named after Pasteur, Strada Pasteur.

REGULATIONS CONCERNING MEDICAL EDUCATION IN JUGO-SLAVIA.

The Jugo-slavian State Board of Health has drawn up a schedule of minimum requirements for the regulation of medical colleges. The conditions of admission to lecture courses are: 1, A certificate of moral character, and, 2, evidence of preliminary education, of which a high school maturity certificate (diploma) represents the minimum requirement. Admission to advanced standing is based upon an equivalence of work done in other institutions recognized by the State Board. The curricula of the medical schools are to embrace four years of instruction, and one year practice in dressing rooms, operating theatres, obstetrical wards, and in clinical wards, aggregating at least fifty months. The branches of medicine to be included in the course of instruction must include at least the following: 1, Anatomy; 2, physiology; 3, chemistry; 4, physics; 5, materia medica and therapeutics; 5, theory and practice of medicine, including ophthalmology, otology, dermatology and neurology; 6, pathology and bacteriology; 7, surgery, including orthopedic surgery; 8, obstetrics; 9, gynecology; 10, hygiene; 11, medical jurisprudence (forensic medicine). The regulations also prescribe dissection, lectures, clinical courses, and regular attendance on the part of the student.

LONDON LETTER.

(*From our own Correspondent.*)

London, *January 23, 1923.*

THE BORDERLINE OF SANITY.

The Middlesex Hospital, London, is about to inaugurate a new departure in this country in hospital treatment. The board of management has decided to open two wards for the special benefit of mental cases in an incipient stage. By arrangement, the patients will be attended by the members of the medical staff of St. Luke's Hospital, the large hospital for the treatment of mental disorders in London. It may be said that under the present British Lunacy Act no provision is made for the treatment of borderline cases, which are frequently of physical origin, or into which the physical factor enters, and which may be treated effectively in the early stages. In any event, the beginnings of mental disorders offer a wide field for systematic investigation, as it is obvious that reforms in the methods of treatment are urgently called for. Intelligent treatment of mental cases is lacking, but recognition is coming that certain forms are susceptible of relief and cure. Therefore, the new departure of the Middlesex Hospital is an encouraging sign of this recognition.

AN EPIDEMIC OF INFLUENZA.

Influenza is widespread but up to the present time is of a mild type, few deaths having been recorded as the result of the disease. In fact, the medical correspondent of the *Times* thinks that there is nothing in the official mortality figures for London to support the idea that the present epidemic deserves the name of influenza which it is generally receiving. The outstanding features, while they vary considerably, are pain of the neuralgic type, a tendency to giddiness, nausea and loss of appetite. The existing outbreak is distinguished by its nervous symptoms and perhaps is the nervous form of a disease which manifests itself in protean forms. At any rate, as yet it is far from deadly, although it is not wise to make definite statements at so early a date. Another feature is a tendency to a rash, which appears on the face and chest, which rash often reappears when a relapse is at hand.

THE PROBLEM OF THE ILLEGITIMATE CHILD.

An influential deputation in regard to the children of unmarried parents bill is soon to be received by the Home Secretary. The death rate of illegitimate children is at least twice as large as that of legitimate children. The fundamental reason for the suffering and dying among such infants is that as soon as an unmarried woman knows that she is pregnant, she is anxious, unhappy, and overcome by every kind of trouble, emotional, physical and economic. The result of the policy pursued in this country is to make the mother the sole support of the child. If a working woman, and the majority of illegitimate children belong to this class, she must not only earn her own living but that of the child. The principle underlying this policy is a deterrent. However, it has failed in this object. There are more illegitimate children born now than ever before, though it has helped to maintain the high death rate and damage rate among the children who are born out of wedlock. In short, there has come to be a very general measure of agreement among those who have studied the question most closely that plans must be changed and the endeavor must be made to compel the father to share the responsibility for the maintenance of the child. An effort must be put forth to try to divide the economic burden more evenly between the parents. Legislation in most civilized countries has been based on this idea, which should give a better chance to the child and should also help to discourage the tendencies towards irresponsible fatherhood. In these days healthy children are a valuable asset to a country, and the presence of a considerable number of illegitimate children, reared and brought up in the conditions usually encountered, is a drawback and a disgrace. It is only in England and Wales of the countries of Europe that it is impossible to legitimatize children by subsequent marriage, and it is hoped that this may be made law in England and Wales. Of all the branches of preventive medicine none is of more importance than child welfare, and it is against the dictates of commonsense that because a child is illegitimate it should be excluded from the benefits of this system.

OBITUARY.

John Tames Pringle, M. D., C. M. Edin., F.R.C.P. Lond., Consulting Physician to the Skin Department, Middlesex Hospital, died at Christchurch, New Zealand, early in December last. He was born at Lannhall, Dumfrieshire, in 1855, and graduated in medicine and surgery at the University of Edinburgh in 1876, taking the M. R. C. P. Lond. in 1884. He was elected a Fellow in 1891. He came to London and joined the Middlesex Hospital in 1883. He was one of the best British dermatologists and a remarkably good diagnostician. As a man he was one of the kindliest, possessing a true genius for friendship. The tales of his charitable acts would almost fill a volume. His work during the war irreparably injured his health, which was never strong, and the voyage to New Zealand was taken as a last desperate chance, but proved futile.

Book Reviews

THE PROPER FEEDING OF INFANTS AND CHILDREN

The Physiological Feeding of Infants and Children. A Handbook of the Principles and Practice of Feeding. By Eric Pritchard, M.A., M.D. (Oxon.), M.R.C.P. (Lond.). Fourth Edition, Entirely rewritten and Enlarged. With Illustrations. London: Henry Kimpton, 1922.

Reviewing is an art by itself. There are reviews and reviews. Some socalled reviewers read the introduction to a book, perhaps glance through the book and pick out a special point or two and then proceed with the review. Some reviewers are nauseatingly fulsome, while others are acutely critical. It goes without saying that it is some advantage to the reviewer and those who read his eulogies, diatribes, or what not, that he should know something of the subject on which he discourses so fluently. Perhaps it is a handicap to know too much, however, for he who possesses an expert knowledge is inclined to be too critical of another man's work in the same direction. The reviewer of Dr. Pritchard's book is not hampered in any of these ways. He knows something of infant feeding, enough to appreciate good writing on the subject, but his knowledge is not so extensive or intimate as to prejudice him in advance against the views of other authorities or would be authorities, and he has an open mind.

This is a fourth edition of Dr. Pritchard's book, which fact, in itself, says something for its worth. It must be understood that the author holds somewhat original views with regard to the proper mode of feeding infants and children. He is called a man of an original mind by those in agreement with his opinions and a crank or faddist by those who disagree or who desire to propagate their own views. For instance, for many years Dr. Pritchard has preached the doctrine, in and out of season, that, as a rule, children and infants are fed too generously, especially babies. It has been a long held belief that infants and young children thrive on "stuffing," that their powers of digestion and assimilation are prodigious, and that it is foolish in the extreme to inveigh against the good old custom of giving a baby something to eat whenever it cries. It is not understood that the little one more frequently cries because it has had too much rather than not enough.

The quantitative question is, perhaps, the keynote of the book, although, of course, due importance is paid to the quality of diet, times for feeding, and so on. The book is based on science reinforced by practical common sense. The author recommends that children be fed according to caloric requirements, but with no slavish adherence to this principle. Such requirements should be regarded from the viewpoints of age, weight, rate of growth, energy production, loss of heat, and various conditions of environment. A physiological basis also must decide the ratio or balance between the different food constituents. From this point of view food should be selected from the aspects of taste, digestibility, absorbability, physical qualities, and variety. Owing to the fact that the last edition of this book was published in 1909, it is obvious that opinions on infant and child feeding have undergone some revision and modification. During the past twelve years the subject has been investigated and threshed out as never before, and it stands to reason that some previously held views have been relegated to the dust heap, or nearly so. Perhaps the most radical change of opinion that Dr. Pritchard has been impelled to make is that he now concludes that it must be wrong to increase the protein content of the food, as the child grows older. He argues thus that breast milk, which is admittedly the best food for infants, does not contain a larger protein content as lactation proceeds for eight or nine months. He thinks the contention that because infants cannot at first digest the full proportion of protein they must necessarily be deprived of their nutritional rights, is just as unsound as it is to assume that when artificially fed infants have developed the capacity for digesting protein they require a larger proportion than is present in breast milk itself. The quantitative basis of feeding is dealt with in respect to children over as well as under one year of age, with due regard to the potent point that knowledge is incomplete with respect to the metabolic processes of children, especially in disease.

However, unfortunately, there is no space here to discuss this book in the thorough manner it deserves to be discussed irrespective of the already acknowledged limitations of the reviewer. But before ending, there are a few points to which attention should be drawn. One of these is the effects of intestinal toxemia in childhood. It may be interpolated here that Dr. Pritchard was one of the first physicians in Great Britain to point out that this condition occurred fairly frequently in infancy and childhood and was the cause of a great deal of ill health and disease, but he holds that constipation or delayed transit are not serious causes of intestinal toxemia in infancy, and so far as the association of intestinal toxemia and constipation is concerned, reliance must not be placed on effecting a cure by insuring regularity of the bowels. Putrefaction or fermentation occurs in the bowel contents when from any reason the food consumed is not digested in the proper place, at the proper time, or at the proper rate by the normal physiological enzymes in the bowel. Among the means for preventing or successfully treating this, dietetic measures hold the first place. Also efficient disinfection of the bowel is recommended.

In the opinion of the reviewer the most valuable chapter of the book is that in which malnutrition and disturbances of metabolism are discussed. Of course, the most important, or at any rate the most greatly talked of condition, coming within this category, is rickets, which rightly enough Dr. Pritchard does not class among the socalled deficiency diseases, that is, deficiency diseases in the narrow sense, those which are deficient or lacking in one or other of the vitamines. Neither does the author assert that the vitamines have little or nothing to do with the causation of rickets, nor does he lay the blame, as many do now, on faulty hygiene and term it a disease of environment. On the contrary, he takes the eminently common sense viewpoint that all these elements are involved to a greater or lesser extent, and that the essential precursor of rickets or the true rachitic state is acidosis and he would prefer to limit the term rickets to the clearly cut syndrome of the three cardinal or pathognomonic symptoms, with a qualifying and distinctive epithet to signify the particular etiological group which is responsible for the causation. For instance, one might speak of an ineffective type, a vitamine type, an endocrine type or a dyspeptic type. A diagrammatic chart included in this chapter clearly represents the causative factors and symptoms of rickets.

The whole book is a well written, plainly phrased exposition of the author's view and, as said before, is distinguished, held in check, and tempered by common sense. The illustrations and diet sheets are to be commended while the appendix is positively a vade mecum for those who desire to feed infants and children on those foods which are best calculated to suit them. The caloric value of different foods is given and the methods of preparing certain foods for infants and children. The work from beginning to end is not only scientific and practical but teems with useful information. It is, moreover, an excellent example of the printers' and binders' craft.

DISEASES OF CHILDREN

The Diseases of Children. Medical and Surgical. Illustrated. By The Late Henry Ashby, M.D. (Lond.), F.R.C.P., and The Late G. A. Wright, B.A., M.B. (Oxon.), F.R.C.S. Revised by Hugh T. Ashby, B.A., M.D. (Camb.), M.R.C.P. (Lond.), and Charles Roberts, M.B., B.S. (Lond.), F.R.C.S. Sixth Edition. Thoroughly Revised and Rewritten. Oxford Medical Publications. London: Henry Frowde and Hodder & Stoughton, 1922. Pp. xxvii-769.

Many years have elapsed since the appearance of a former edition of this textbook. Pediatrists and general practitioners will welcome the present sixth and revised edition. Much progress has been made in the field since the appearance of the last edition in 1905 and most of the text had to be revised. All in all, it is a new book and a worthy one as a standard textbook. In some respects it differs from some American conclusions, in regard to feeding, for example, but these very differences deserve careful consideration.

FRACTURES

On Modern Methods of Treating Fractures. Including the Jacksonian Prize Essay on Bone Grafting. By Ernest W. Hey Groves, M.S., M.D., B.Sc. (Lond.), F.R.C.S. New York: William Wood & Co., 1922.

Like all new works and new editions this book contains a great mass of information derived from the war experience. In gleaning the knowledge here embodied the author had the advantage of close associations with Sir Robert Jones and his pupils. The author believes that the study of fractures, their mode of production and their management, should constitute a specialty as distinct as those dealing with diseases of the eye, throat, or other parts of the human frame, and "until fractures cease to be the mere encumbrances of general surgical wards, no great progress can be made in knowledge, treatment, or teaching." The book is very profusely illustrated in black and colors, and we may add, appropriately illustrated, not one of them being superfluous or introduced merely for effect or as padding. Groves has definite opinions of his own regarding the treatment of fractures and he does not hesitate to express them, but he has also been hospitable to the views of others and describes very fully and satisfactorily the various methods advocated by other surgical authorities. The book should find a place in the library of every man in general surgical practice or whose field of activity is more or less remote from medical centres, for it will on occasion be found a friend in need.

CARDIOLOGY

Diseases of the Heart. By I. Harris, M.D., L.R.C.P. (Ed.). New York: William Wood & Company, 1922.

The avowed object of the book is to give a complete account of cardiology, old and new, in as concise a form as possible. In effect, the author confines himself to a didactic presentation of the elementary facts concerned in the diagnosis and treatment of diseases of the heart. The references to cardiac physiology and pathology are scanty. A number of statements presented as facts will be questioned by many. For instance, that a systolic pressure of 160 is invariably due to kidney trouble; that rheumatic endocarditis is caused by a streptococcus and may be either simple or ulcerative. Completeness has often been sacrificed to brevity. Thus no mention is made of the thrill in aortic stenosis. The note on the employment of quinidine in auricular fibrillation is too short to be of value to one not acquainted with more detailed accounts of its use. No references to the literature are given. The book may have some value as a quiz compend for medical students.

COLLOIDAL SOLUTIONS

The Physical Properties of Colloidal Solutions. By E. F. Burton. Longmans, Green & Co.

The second edition of the *Physical Properties of Colloidal Solutions* has been thoroughly revised and the subject matter brought strictly up to the date of publication. Recent advances in the knowledge of colloidal chemistry have made it necessary to rewrite entirely certain parts of the book. The volume is intended primarily for the student of physics, and the author has emphasized the relation of colloids to the development of physics. A considerable, but not undue, space is devoted to the discussion of the purposes and use of the ultramicroscope, and to the confirmation of the kinetic theory of matter afforded by the study of Brownian movement. The student of chemistry, as well as the physicist, will be interested in the chapters dealing with the phenomena of the charge possessed by the colloid particle, surface tension, and the mechanism of coagulation. The latter subject is discussed in the light of the latest studies, and the chapter has been entirely rewritten. The section dealing with the practical applications of colloidal solutions is unfortunately short, but as the author writes in his preface, this topic requires a whole treatise in itself. The volume under review is one of a series of monographs on Physics, and maintains the high standard set by the earlier issues.

BIOLOGICAL SOCIETY OF BARCELONA

Treballs de, la Societat de Biologia. 1919. Publicacions de l'Institut de Ciències. Publicats sota la direccio de A. Pi Suner. Barcelona: Institut d'Estudio Catalano, 1919.

Thirty-five papers were read before the Biological Society of Barcelona at its various sessions during 1919, the transactions being as usual published in Catalan Spanish. The society has at present forty-seven active members, of whom twenty-five read papers alone or in collaboration. The subjects show notable variety, and some of interest to the clinician are devoted to spirochetosis, uterohemorrhagica, gas gangrene, syphilis, tetanus, spastic paraplegia, anaphylaxis, the peptone treatment of infections, influenza, pyocyaneus infections, and glycosuria. Others deal chiefly with problems of embryology, physiology, and biochemistry. The most significant title deals with the intratracheal injection of antipneumococcus and antistaphylococcus serum in the pulmonary complications of influenza by Bossan. The author punctures the larynx and throws the serum directly into the trachea. He relates five cases in which the treatment caused a brusque defervescence. In two others the patients were in extremis. In the other eight the patients recovered, but the author does not regard the latter of crucial importance, for they would doubtless have recovered in any case.

REGIONAL ANESTHESIA

Regional Anesthesia. Its Technic and Clinical Application. By Gaston Labat, M.D. With a Foreword by William J. Mayo, M.D. With 315 Original Illustrations. Philadelphia: W. B. Saunders Company, 1922.

Europe is somewhat in advance of America in the use of the various methods of injection anesthesia, probably owing to the better control of the patient abroad and the complacency of the latter. William J. Mayo, in his foreword to this book, says that he does not look forward to the day when regional anesthesia will wholly displace general anesthesia; but undoubtedly it will reach and hold a very high position in surgical practice. The fact that there is a chair of regional anesthesia in two of the leading teaching institutions of the country shows that this field of practice is pregnant with possibilities.

The author aims to impart the means of acquiring rapidly a practical knowledge of regional anesthesia and he does this in a most approved manner, basing his work on a personal experience gained in thousands of cases. This is a field of practice where practical experience and a thorough knowledge of anatomy are absolutely necessary. It is of such broad application that it needs no wide stretch of imagination to see the possibility of regional anesthesia becoming a specialty in itself. The surgeon of the future must either master it himself or cooperate with a specialist in regional anesthesia.

The author divides the entire body into various regions from the viewpoint of nerve distribution. The choice of the operation is left to the surgeon. The most detailed instructions are given as to the method and technic of the various procedures. The surgical anatomy of each part to be anesthetized is given in detail. The illustrations are original, very apropos and most instructive and the language is direct. The book is intensely practical. Special chapters are devoted to otology, rhinology and laryngology, urology and dentistry. The technic of intraspinal block, socalled spinal anesthesia, is also discussed in full.

The results obtained with this form of anesthesia are well worth the time and effort spent in acquiring its technic, which should be mastered by everyone attempting to do major surgery. Future progress in anesthesia undoubtedly lies in this direction. The scope of the operations possible with regional anesthesia depends upon the experience of the surgeon. It reduces the operative prognosis to a minimum by not affecting the vital functions of the main organs of the body and also the direct inconveniences and dangers of inhalation anesthesia; it also forces gentleness in the handling of the tissues on the surgeon. Novocaine, in strengths of 0.5 to two per cent., is the anesthetic drug of choice, the strength varying with the nature and region of the operation.

THERAPY

Grundriss der klinischen Therapie innere Krankheiten. Von Prof. Dr. Georg Klemperer, Director der IV medizinische Universitätsklinik, ärztl, Direktor des städt. Krankenhauses Moabit in Berlin. Price 108 marks. Berlin and Vienna: Urban & Schwarzenberg, 1922.

The author, with whom Dr. L. Dünner has collaborated in getting out the present volume, divides his subject matter as follows: general treatment of the sick individual; infectious diseases; diseases of the digestive, respiratory, cardiovascular, renal, hemic, arthric, and nervous systems, disorders of metabolism and poisonings. A formulary is appended. The author has for many years edited the periodical *Therapie der Gegenwart*, and is one of the best known therapeutists in the world. An extensive formulary is appended.

CONDUCTIVITY AND PERMEABILITY

Injury, Recovery and Death, in Relation to Conductivity and Permeability. By W. J. V. Osterhout. Philadelphia and London: J. B. Lippincott Company. Pp. 20-259.

This book may to many seem to be a useless task —for the present. But there is no doubt that work of this character is going to help us some day solve, if not the problem of life, at least some of the more fundamental underlying factors. The scope of usefulness of this monograph will increase as our knowledge broadens. For the present we can only study the results as set forth on the chance that they may give us clues to which we can add or that they may serve to stimulate us along to further efforts at the solution of that great mystery, life.

PIRQUET SYSTEM OF NUTRITION

An Outline of the Pirquet System of Nutrition. By Dr. Clemens Pirquet. Philadelphia and London: W. B. Saunders and Company, 1922. Pp. 96.

An authoritative statement of the Pirquet system of nems, including the nutritional treatment of tuberculosis and feeding as preventive medicine. Much of this material has appeared in the New York Medical Journal and, no doubt, our readers will welcome the appearance of this useful monograph.

MIND ENERGY

Mind Energy. By Henri Bergson. Translated by H. Wildon Carr. London and New York: Macmillan & Co., 1921.

Diverse topics are discussed in this series of essays. Some of the themes were first presented as far back as 1901 (*Dreams*) yet in every instance much will be found that is valid and full of interest. Few philosophers, with the exception of James, have had so much in common with the medical man. A more appropriate title for Bergson would be a philosophical psychologist. Most farreaching are his ideas on consciousness, and his working out of the unconscious which is so important in the understanding of modern psychopathology.

The chapter on memory of the present and false recognition takes up an interesting study which has engaged the minds of most leading psychiatrists in the past. Bergson's hypothesis is ingenious. His style varies from brilliance to an involvement of presentation most difficult to grasp and untangle. How much of this is due to difficulties of translation is hard to say. On the whole, the book may be classed as a distinct contribution to the realistic school of philosophy.

DIAGNOSIS OF NERVOUS DISEASES

Diagnostica delle Malattie Nervose. Dott. G. Mattirolo. Libero docente di Patologia Medica e di Neuropatologia in the University of Torino. Torino: Unione Tipografico-Editrice Torinese, Milan, Naples, Rome, 1920.

This book offers a well outlined presentation of the anatomy of the nervous system and of the localization of disease processes within it. In concise form it sets forth the forms of disease to which the nervous system is subject. Its manner is such as to make this knowledge most accessible to the practitioner who needs just such aid in his frequent duty of diagnosing such conditions. It forms a useful reference book for ready consultation by anyone interested in the structure, function and pathology of the nervous system. It does not attempt more than a brief entrance into each portion of its subject. Yet merely in the way of stimulus in that direction it should have laid more emphasis upon the psychic background of nervous disorders. This is always, and in hysteria most especially, to be considered.

MAN'S SUPERSTITIONS

The Origin of Man. By Carreth Read, M.A. Cambridge University Press, 1920.

Read has given us an unusual contribution on the superstitions of man. His basic approach is anthropological, yet he considers carefully the psychological and philosophical aspects. To call Read a pessimist would be unfair, yet it would not take much to make him one. This does not mean that he has not made a most valuable contribution. His book is replete with well selected data of value which he has considered with care and worked up into a valuable whole. He is at variance with most anthropologists regarding the priority of animism and magic. The evidence, as he presents it, sounds plausible. Read has a faculty of placing his finger on the shortcomings of man's development. He fears we have clung too long to archaic beliefs and in so doing have prevented our own development. When we consider the furore made over a sorcerer like Coué, we are inclined to agree with him, but when we examine the growth of modern analytical psychology, we feel that man will soon come to a better understanding of self and so be able to rid himself of his regressive superstitions.

On the whole, Read's book should receive careful study as it is a real contribution to the history of human thinking and belief.

MENTAL DISORDERS

Mind and Its Disorders. By W. H. B. Stoddart, M.D., F.R.C.P. Fourth Edition. Philadelphia: P. Blakiston's Son & Co., 1922.

The author's mind has been in a state of revision and he has been honest enough to admit it and revise his book accordingly. For this reason, and because he is one of the best grounded psychiatrists, his book is one worthy of careful consideration. In this, the fourth edition, numerous changes have been made as the author gives increasingly more credence to psychological rather than to organic causes in the formation of the psychoses and psychoneuroses. In many instances he still clings to older concepts but not as tenaciously as formerly. In all it is a good book by a very big man.

MEMORY

Remembering and Forgetting. By T. H. Pear, M.A., B.Sc. New York. E. P. Dutton & Co., 1922.

A description of memory as formulated by the psychoanalytical school. An attempt is made to temper some of Freud's concepts by the use of terms designed by the late W. H. R. Rivers. A considerable amount of experimental psychological material is introduced. If the book can be classified it should be placed in the transition group standing between the old and new psychologies. The author has been reluctant to give up the old and somewhat timorous of accepting the new.

ITALIAN SURGERY

Modern Italian Surgery and Old Universities of Italy. By Paola De Vecchi, M.D. New York: Paul B. Hoeber, 1921.

An interesting description of the surgery of the modern Italian School is this volume, in which Dr. De Vecchi describes many methods recently devised in Italy, some of them in detail. Of especial interest is the cosmetic operation of Vanghetti, which aims to preserve the amputation stump so it may be usefully employed after the operation. The book is attractive and should be of great interest to the American surgeon.

REFERENCE HANDBOOK FOR MEDICAL OFFICERS

An Outline of the Medical Service of the Theatre of Operations. By M. A. W. Shockley. Philadelphia: P. Blakiston's Son & Co., 1922.

This is a book designed for reference for the line, general staff and medical officers. It is purely technical in its scope and conforms with the new army organization and new medical service nomenclature. The book has undoubtedly been worked out through the organization of the medical staff.

PASTEUR INSTITUTE MONOGRAPHS

Monographies de L'Institut Pasteur. Pneumocoques. Et Affections Pneumococciques. L. Cotoni, C. Truche et Mlle. A. Raphael. Paris: Masson et Cie, 1922.

This monograph presents a summary of the researches carried on in Nicolle's laboratory during recent years. The work is divided into three parts—the first one dealing with the bacteriology and immunology of pneumococci; the second part with the distribution of pneumococci and the diseases which they may provoke; the third part with the treatment of pneumococcal infections. The material is very well presented and contains abundant references to the literature. It is particularly interesting to note that their studies do not support the idea of the four distinct groups of pneumococci, which have been described by American observers. Their studies of active and passive immunity lead them to believe that there are no distinct types of pneumococci. The groups that have been described are characterized only by their agglutination reactions but not by their antigenic powers. All pneumococci contain the four antigens. Agglutination is a poor method of recognizing these antigens. Thus a powerful type I serum may cure patients who are suffering from a pneumococcal infection of a different type. In the last part of the book the serotherapy is discussed and good results are reported from the use of antipneumococcus serum prepared along the lines pointed out in their researches.

A NOVEL OF THE CIVIL WAR

Proud Lady. By Neith Boyce. New York: Alfred A. Knopf, 1923.

There are several features of this novel of the Civil War that raise it above the commonplace "good" novel of the present day. It is a study of two characters, each distinctive for reasons well understood by the author. They marry; they struggle for years to reach an adjustment. Their married life is the typical life of thousands—content enough outwardly, yet hampered by inward strife, dissatisfaction. They realize too late that their mating had been preordained; that they were capable of true happiness in their love life. It is the breaking down of their love life and the lonely years following upon the crash that brings them to knowledge. And then, of course, it is too late, for the bulwark of pride, injured selfrespect, socalled, takes the place of the stubborn adolescent ignorance to which they cling for more than half their wedded life.

The girl as a result of her mother's training is a repressed puritan. The man coming back to his betrothed after the Civil War has undergone the same growth that is causing constant new problems for the present generation. Naturally they can no longer meet on a common basis. They compromise and drift along, each leading a separate inner life that has no contact with that of the other. We have not progressed very far beyond this same picture. For that reason the story will long endure as a careful history of marriage as it has been for many years and as it will remain for many years longer, unless the bonds of tradition, convention, the lying outwardness of "good form," can be broken to let reality of feeling, emotion, honest selfknowledge reign in their stead.

DITTE

Ditte—Daughter of Man. Ditte—Towards the Stars. By Martin Anderson Nexo. Translated from the Danish by A. G. Chater and Richard Thirsk. New York: Henry Holt, 1920.

The tragedy of Ditte, begun so appealingly in *Ditte—Girl Alive,* unfolds through these two latest powerful volumes. The inevitable life pattern followed by the little illegitimate girl is reiterated through her years of service, toil, misfortune. Through it all she carries her heart of gold. But it is of no avail. The frightful conditions of the very poor in any European city overwhelm her just as countless other victims of our age of exploitation. The pictures of conditions in farmlands in Copenhagen among the poor everywhere, in short, are ruthless. They haunt one. They *must* awaken the slumbering spark of humanity in us. As a propagandist Nexo is indeed a moving spirit. May his long struggles for better conditions among the working classes in his country be at last crowned by success!

Perhaps it is the very mother spirit in these unfortunates that makes the struggle increasingly difficult. From the outset they accept their inferiority. Self-sacrifice, intolerable hardship, helpless victims of life, they make no effort. It is preordained. They are passive and suffer in silence. Pelle's genius crested a wave of progress in the struggle. An advance was made; one of the rhythmic manifestations of natural ebb and flow of economic conditions. Already in Ditte's day and neighborhood the apathy is growing. The tide shrinks back from the outposts Pelle has set up leaving them as silent tombstones of a hope.

LONDON

The London Spy. By Thomas Burke. New York: George H. Doran Company, 1922. Pp. 324.

A misleading title for a charming book. Whimsical sketches of spots in London here and there, of people, celebrities and those obscure in their own circle are done in the inimitable Burke fashion. There are anecdotes which sparkle with a dry humor and of interest to Americans. if not to every one, is a short, intimate psychological portrait of Charlie Chaplin. There is also a sketch of a London cinema studio which throws some new light on the character of the people engaged in the work and of the work itself. Burke is a keen observer; his philosophy mingles with his studies making the reading of his books both profitable and enjoyable.

HISTORY

The Story of Mankind. By Hendrik Van Loon. New York: Boni & Liveright, 1921.

Van Loon has animated history both in his manner of telling it and by his pungent illustrations. His book is written for children but no one can read it without having a finer vision of the historical background that has brought us to our present day civilization. Most important of all, his historical facts are nearer to being accurate than those of most other ponderous historical volumes. He has unquestionably demonstrated how the study of a subject, considered as dry as history has been in the past, can be made vital and enjoyable.

Medicoliterary Notes.

Paul Claudel, author of the mediæval miracle play, *The Tidings Brought to Mary,* recently presented in New York by the Theatre Guild, is not only a dramatist, but a poet, a mystic, and a statesman. He has held some of the most important posts in the French consular service, among them those of Vice-Consul in New York and in Boston, Consul at Shanghai, China, at Frankfort and at Hamburg; he has been Minister to Brazil and to Denmark, and is now French Ambassador to Japan.

* * *

Dr. E. H. Lewinski-Corwin is the writer of two interesting articles about New York medical matters that have appeared in recent periodicals. "The Academy of Medicine's Contribution to Public Health in New York City" is the title of one in the *Nation's Health* for December, 1922; and "New York as a Hospital Centre," in the *Modern Hospital.*

* * *

A Sick World is the title of an interesting and sane article in the *New Republic* for January 24th, written by John Dewey. Couéism is defined as "an appeal and a method as old as the caveman but dressed up in the latest fashions of the day." He warns against the danger of such socalled cures, especially of the kind of mental processes which make them possible. He writes: "When one compares the benefits of the relief that some sufferers will obtain at Coué's hands and voice, with the harm done by increased dependence upon blind clamor and undiscriminating rumor, by habits of increased unintelligent response to stimuli that owe their force simply to their sensory and emotional accumulation, when one thinks of the growth of credulity and the abandonment of judgment, the balance on the side of benefits is not impressive."

Under the terms of a bill introduced in the lower house of the Legislature, mentality equivalent to that of a child of twelve must be a requisite to marriage in Oregon. The bill requires all applicants for marriage licenses to submit to physical and psychological examinations, rules and regulations for which are to be formulated by the State Board of Health. Failure to pass the required examinations would preclude the issuance of a marriage license unless one or both parties submit to sterilization.

Practical Therapeutics

BACTERIOLOGICAL BEEF PEPTONE AS A THERAPEUTIC AGENT IN PEDIATRICS*

By F. Raoul Mason, M. D.,
New York,

Associate in Pediatrics, New York Post-Graduate Hospital and Medical School; Assistant Attending Physician, Babies' Ward, New York Post-Graduate Hospital, etc.

The substance we are dealing with in this paper is not a simple chemical compound, as its name might indicate, but a mixture of proteoses, peptones, polypeptids and aminoacids resulting from the digestion of beef by pepsin or pancreatin. It is a product used extensively in bacteriology under the name of beef peptone for the preparation of culture media.

In the past beef peptone was advocated as a food for invalids, with the belief that in this form proteins would be more easily digested. This theory has apparently not been substantiated and is gradually falling into disuse. It is perhaps worth noting also that many of the pepsin preparations on the market, by the time they are administered to the patient, contain very little active ferments and really consist simply of peptones. In this paper I shall attempt to explain the use of beef peptone for an entirely different purpose, and in order to get a better understanding will briefly review the recent literature dealing with this subject.

During the past few years beef peptone has been employed extensively in Europe, 1, as an antianaphylactic agent (if such a term may be used) and, 2, as a nonspecific protein. Nonspecific protein therapy is not a new therapeutic discovery, in fact, milk was used intravenously quite extensively in the seventeenth century in England in the treatment of a variety of pathological conditions. As far as we can judge, at the present time, satisfactory results were obtained, but this procedure had to be abandoned because of the frequency of emboli. Lately, nonspecific protein therapy has again been brought forward and while it is not a panacea for all ills, has proved useful in certain chronic infections, skin conditions, arthritis, anemias and even acute infections. The mechanism is still very obscure and we would be deviating from our subject by going into details.

Beef peptone has been used to cause a nonspecific reaction by several clinicians, in particular by Nolf, who believes this substance to be superior to proteins because of the immunity of any severe anaphylactic shock following its administration.

Beef peptone as an antianaphylactic agent was first discovered, accidentally I believe, at the Pasteur Institute in Paris. It was found that the preliminary injection of peptone into a guineapig or a rabbit protected the animal from a lethal dose of a protein to which they were sensitized. It seemed, therefore, that the administration of beef peptone prevented the appearance of anaphylactic phenomena. It is only fair to say that constant results are not always obtained when other species of animals are used, but, on the strength of these and similar investigations, several French clinicians attempted to employ beef peptone to ward off certain obvious forms of alimentary anaphylaxis and the results they obtained in many cases were very satisfactory.

The experiments of Pagniez and Vallery Radot probably explain better than anything else the mechanism brought into play. They described a number of cases of alimentary anaphylaxis showing an intolerance to eggs, milk, shellfish, etc., giving rise to such anaphylactic manifestations as migraine, angioneurotic edema, and urticaria, and were able to prevent the occurrence of these disturbances by giving, one hour before the ingestion of these foods, a minute quantity of the harmful substance (just as we temporarily desensitize patients to horse serum by giving them a few drops of diphtheria antitoxins an hour or more before the administration of the full dose). By substituting 0.5 gram of beef peptone to these various substances, one hour before the meal, they obtained similar results. They concluded, therefore, that, as far as temporary desensitizing was concerned, beef peptone was polyvalent for most of the foods causing anaphylaxis. Similar results have been reported by other authorities, and while this method is not uniformly successful, on the whole it has given satisfaction to those who have used it.

In Italy, Solverini also tried beef peptone as an antianaphylactic measure in children sensitized to horse serum following the administration of diphtheria antitoxin. He was able to prevent the appearance of any anaphylactic manifestations in twenty-six children, giving positive skin reactions by injecting them, a day or so before they were tested again, a five per cent. solution of beef peptone (ten to fifteen centigrams to the kilogram of body weight).

Auld, in Great Britain, has employed this substance quite extensively by hypodermic injections in the treatment of bronchial asthma. He divided his cases into two groups, one in which the patient responded to these injections, more or less permanently, and the other in which the patients were not in the least benefited by them.

My own experience with this substance goes back a little over two years, during which time I have tried it out, both by oral and by hypodermic administration in about two hundred cases of asthma in children, in a certain number of other forms of anaphylaxis, and finally in cases in which there were apparently no anaphylactic bases. I am using, after trying out various combinations, at the suggestion of the druggist of the Post-Graduate Hospital, a solution of beef peptone in glycerine and water. This makes a clear solution which can be filtered and sterilized in an autoclave or by boiling in a test tube. In subcutaneous hypodermic injections I have tried it out in psoriasis, eczema, chronic urticaria and bronchial asthma. By mouth, I have given it in a variety of gastrointestinal conditions, asthma, urticaria, psoriasis, eczema, and various skin disorders. Briefly, I will review my experience in these various disorders.

PSORIASIS.

By mouth, one hour before meals, beef peptone has been of very little value. By hypodermic injections (thirty-three per cent. beef peptone, twice a week) in the few cases I have tried it has been very satisfactory. In view of the well known tendency of this disease to clear up of itself very suddenly, I do not feel justified in making too definite a statement. However, it has seemed to me to be more than a coincidence that after such injections (and only after a local reaction had occurred at the site of the injection) the patches of psoriasis would lose their fiery red color, become brownish, peel off and fade more or less rapidly, while new lesions which had been appearing daily, ceased to come out.

---

*From the Pediatric Department, New York Post-Graduate Medical School and Hospital.

ECZEMA.

It is well to remember, that in nearly every case of eczema, there is a superimposed infection, and unless this is treated, the removal of the primary factor alone will not cause this condition to disappear. However, in those cases of eczema of anaphylactic origin, a teaspoonful of a ten per cent. solution of beef peptone one hour before meals has often caused the disappearance of an eruption previously rebellious to the usual methods of treatment.

URTICARIA.

In the acute cases beef peptone is obviously of little value as the patient will not, as a rule, take the trouble to follow up the treatment. In the chronic type, however, a small quantity of beef peptone by mouth one hour before meals will, in about one third of the cases, cause the eruption to disappear quite rapidly. Hypodermically, the effects do not seem to warrant its use.

BRONCHIAL ASTHMA.

Peptone by mouth does not improve the real asthmatic symptoms, though it will often cause an improvement in appetite and a gain in weight. In a certain number of selected cases the injection of from one to three minims of a thirty-three per cent. beef peptone will result sometimes in spectacular results, while more often it will cause a decrease in the symptoms particularly the constant cough so often noticed in asthmatic children. Asthma due to emanations, however, if these emanations are not removed, will not be benefited in the least by this method of treatment. The best results are obtained in patients who do not give any positive skin reactions to the various foods or emanations, or those in which no improvement is noticed after the removal or desensitization to the offending proteins. A certain number of such patients are improved by vaccines alone. It is among this group that the best results are obtained with beef peptone, in fact, I believe that some of the results obtained with vaccines are perhaps due to the fact that they contain a certain amount of peptone. However, in certain cases the patients will not improve under beef peptone and will do well with an autogenous vaccine, while some are rebellious to autogenous vaccines and clear up under beef peptone. I am quite convinced, however, that if no improvement is noticed after the second or third injection, it is useless to keep up this method of treatment. Beef peptone injections are not indicated in all cases of asthma, they are only advisable when the common methods of controlling this disease have failed.

HAY FEVER.

The results do not warrant its use in this condition.

GASTROINTESTINAL UPSETS.

In a certain number of recurrent cases of vomiting, diarrhea, nausea, cramps after meals, and also in malnutrition and lack of appetite, symptoms so common in childhood, beef peptone by mouth, one hour before meals, will often result in rapid improvement. Not all these cases give a clear anaphylactic history and it is hard to say beforehand in exactly what cases it should be employed.

NONSPECIFIC PROTEIN THERAPY.

While I have not used it extensively in this respect, occasionally it gives good results, probably as well as any other protein.

A few examples from private practice and hospital will perhaps make this a little clearer:

Case I—C. W., aged ten, female, of German descent. For two years the patient had been suffering from psoriasis, which was particularly extensive on arms and legs. The scalp was full of large scales which were forming continually. She had been to various skin clinics and systemic and local treatment (arsenic, etc.) had been tried with no improvement. She was given injections of a thirty-three per cent. beef peptone solution once a week, increasing one drop each time. After the second injection it was found that new patches failed to appear, and following the third a distinct change for the better was noticed. No local treatment of any kind was given. The dose was increased to five minims, but as it caused a rather severe reaction was reduced. At this time the scalp began to clear up, and soon was free from scales for the first time in two years. After the sixth injection treatment was discontinued, as the patches were rapidly fading away. For several months after this improvement continued so that only a few very small stubborn areas were left. At this time, however, several new small patches were noticed and two minims of a thirty-three per cent. beef peptone were then administered twice a week. This rapidly caused all the skin lesions to disappear entirely, and the child has been well ever since. It is of particular interest that the scalp is particularly clean and that there is now not even the slightest dandruff.

Case II—P. R., boy, aged ten, of Jewish parentage. He had suffered from bronchial asthma for several years, with constant cough and attacks several times a week. Skin reactions were negative and the usual methods of treatment, including autogenous vaccine, failed. Positive D'Espigne sign to third dorsal and the x ray revealed a mediastinal adenopathy. He was sent to the country for several months, with marked improvement. On his return, however, the symptoms recurred as severe as ever. He was given beef peptone injections once a week, going from one to four minims. Under this treatment the cough practically disappeared, the boy gained in weight and for the last four months has had only one mild attack of asthma.

Case III—A. S., aged eighteen months, male, of Italian parentage. He had had chronic urticaria since eight months of age. Was given half a teaspoonful of a one tenth per cent. beef peptone solution one hour before meals. Within one week the urticaria had practically disappeared.

CASE IV—J. S., aged two and an half, male, of Jewish parentage. He had always been a difficult feeding case and could not tolerate cow's milk, and as he had reacted to lactalbumen, was brought up on dryco. Never in his life had he had a real hard stool. In spite of the strictest diet, he had had recurrent attacks of diarrhea, which would last for a week or more and would cause considerable loss of weight. Finally beef peptone was given to him in a ten per cent. solution, one hour before meals. This prevented any recurrence of the diarrhea for several months, but the stools never became hard. The mother went away for the summer and the peptone was discontinued. Two weeks later diarrhea recurred and was checked by a special diet and beef peptone. In the fall, peptone again being discontinued, another attack of diarrhea developed. The child was then tested and gave a positive reaction to lactalbumen and several foods. Calcium caseinate (casec) and water for twenty-four hours was prescribed, which checked the diarrhea. A fairly liberal diet was given and previous to each meal twenty drops of a twenty per cent. beef peptone and five drops of raw cow's milk administered. For the first time in its life the baby had a solid stool, and since then has been thriving. In this case apparently beef peptone alone did not desensitize completely, as evidenced by the presence of somewhat loose stools.

CASE V—J. A., male, seven years old, of Jewish parentage. He was undernourished and complained of abdominal pains, mostly after meals. The diagnosis of chronic inflammation of the appendix (as is often the case) had been made. Several examinations, including a rectal, failed to show any real appendiceal tenderness or rigidity. Laxatives failed to improve the condition. He was given one teaspoonful of a ten per cent. beef peptone solution one hour before meals. This caused the pains to disappear. Several months afterwards the boy came back. He had been doing well until the medicine was stopped, and even for a little while after, but lately the symptoms had recurred.

In order at least to obtain an inkling of what was taking place, I carried out several experiments. The only finding of any interest is that an abnormally large number of anaphylactic children—I would say over fifty per cent.—gave a positive skin reaction to beef peptone (regardless of the fact that it has been given to them or not), while normal children rarely do. For instance, I tested, with the permission of Dr. LaFetra, twenty-five children on his service last winter in the baby wards of the Post-Graduate Hospital, and of these only two gave a faint positive reaction. I was unable to see the parents of these children to obtain any definite anaphylactic history. It seems to me that it is because the protein tested is in this partly broken down stage that this occurs, for egg peptone, tested side by side, though not always giving identical findings, did so quite often. These are the only two peptones which I have been able to obtain so far, but it is at least suggestive.

One other possible explanation of the action of beef peptone is to be found in the recent papers of Widal and his coworkers. He states that normally the portal vein from the intestines contains proteins, and partly broken down proteins as well as aminoacids. One of the functions of the liver, he believes, is to change these partly digested substances into aminoacids, so that they enter the blood stream as harmless compounds (aminoacids will not cause anaphylactic reactions). In pathological liver conditions Widal has shown that during the early part of digestion this proteolytic function of the liver lags behind and that compounds more complex than aminoacids actually enter the systemic circulation. This causes a protein reaction of what Widal calls a hemoclasic crisis, that is, a physiochemical change in the composition of the blood stream. Upon the fact that the individual is sensitized or not to this particular protein will depend the severity of the resulting symptoms. Apparently the administration of a small quantity of beef peptone, one hour before meals, will start the proteolytic function of the liver, so that by the time the unbroken proteins of digestion are taken up by the portal vein they are easily taken care of.

Whether these theories are proved to be correct or not, it is certain that in a certain number of cases results are obtained by its use. It is a simple therapeutic measure, the preparation is easy to make, keeps well if a small quantity of alcohol is added to it, and can quickly be sterilized if it is desirable to give it subcutaneously. As a safe measure, however, whenever it is to be given hypodermically, I believe that no more than one minim should be given the first time and the patient watched for about ten minutes afterwards.

CONCLUSIONS.

Beef peptone, mixed with glycerine in water (always mix with the glycerine first), can be given by mouth or hypodermically for the following purposes.

1. As an antianaphylactic agent, either by mouth one hour before meals, or by hypodermic.
2. To start the various functions of digestion of the proteins (particularly that of the liver) and thus facilitate their assimilation, by oral administration before meals.
3. As a nonspecific protein, by hypodermic injections.

Proceedings of Societies

AMERICAN PEDIATRIC SOCIETY.

Thirty-fourth Annual Meeting, Held in Washington, D. C., May 1, 2 and 3, 1922.

The President, Dr. Maynard Ladd, of Boston, in the Chair.

(Concluded from page 606, Vol. CXVI)

The Significance of Clinical, Radiographic, and Chemical Changes in the Early Diagnosis of Rickets.—Dr. Alfred F. Hess, of New York, asserted that rickets was essentially a systemic disease and it had become very difficult to say whether it was present or not. For the past four or five years he had had an opportunity to follow a number of infants month by month and to note the signs of rickets as they developed on different diets. They had found the clinical signs of rickets very variable. For instance, the development of the teeth was not to be relied upon, since in some children with rickets they developed early, in others late. The question of when the child began to sit or stand, the question of musculature, and of craniotabes were all unreliable as signs of rickets. Beading of the ribs was the best clinical sign of rickets. It was, however, a poor sign as regards the cure of rickets, since it persisted in spite of the use of codliver oil and the ultraviolet rays. They had found that in the winter it took three and a half months to cure rickets by means of codliver oil, while in the summer, when they had the additional factor of light, it took only two and a half months to effect the same result. In an infant over a year old beading of the ribs had little value as a sign of the development of rickets, for when the Harrison groove appeared the beading disappeared.

Dr. Hess expressed disappointment in the x ray. He had found that the change in the epiphyses was a late sign of rickets, the beading of the ribs being noticed much earlier. The condition of the developmental centres and the calcification of the shaft of the bone were also unreliable signs. On the other hand, in regard to cure the situation was quite different. When one gave light therapy or codliver oil, within two weeks or certainly within a month, there was marked calcification of the epiphyses so that the röntgen ray was the most reliable test by which to determine whether a therapeutic method was efficacious.

The normal inorganic phosphate, according to the method of Doig and Bell, varied from four to four and a half mg. and amounts below 3.75 were considered as indicating the presence of rickets. He had found that this change in the phosphate content of the blood came about considerably earlier than changes that could be detected by the röntgen rays, and sometimes sooner than beading. He had found that when whole milk was given the beading came earlier than the lowering of the phosphate. Whether a low inorganic phosphate content was to be judged a pathognomonic sign of rickets was difficult to say at the present time. It had been noted that in the winter months the inorganic phosphate content decreased and in the summer it rose. This socalled seasonal tide in the phosphate content seemed not entirely associated with rickets. The phosphate content rose very rapidly as the rickets improved.

As to the treatment, in addition to codliver oil and the ultraviolet light, the carbon arc light had been found very efficacious in the treatment of rickets. The carbon arc light could be used immediately for one hour, whereas the ultraviolet light could be employed for only a few minutes at first.

Factors Concerned in the Calcification of Bone.—Dr. John Howland and Dr. Benjamin Kramer presented this communication, which pointed out that calcification consisted essentially in the deposit of calcium phosphate in the cartilage and bone. To bring about this deposition a certain minimal concentration of calcium and inorganic phosphorus must be present in the serum. The concentration of these substances in the serum of rachitic children has been determined. Evidence of calcification has been obtained by radiographic and anatomical studies. By comparing the information gained in these different ways it is possible to say that failure of calcification may result from a diminution of calcium or of phosphorus or both of these in the serum and to state approximately the limit of concentration below which calcification does not occur.

An Unusual Case of Mediastinal Tumor.—Dr. Thomas B. Cooley, of Detroit, recorded this case, which occurred in a boy, seven years of age, who was admitted to the Children's Hospital on February 2, 1922, with a history of having had a sudden attack of severe dyspnea the night before. The family history was negative. The hospital records showed that the boy had been in the hospital for a few days in 1919, with a diagnosis of bronchitis. Nothing was noted at that time except that the breathing was labored. Physical examination showed that the left upper chest seemed fuller than the right and there was a plexus of enlarged and superficial veins in this region. A node the size of a pea was found in each axilla. Percussion of the chest revealed an area of pronounced dullness extending from just outside the left nipple line nearly to that on the right, with fairly straight borders, and reaching from the level of the clavicles to the diaphragm line. The greatest transverse diameter was twelve mm. On auscultation the breath sounds were greatly diminished. X ray examination of the chest showed an area of pronounced density corresponding closely to that outlined by percussion. The mass seemed to fill more than half the thorax. A provisional diagnosis of Hodgkin's disease, thymus gland disease, or lymphosarcoma was made. One of the axillary nodes removed later showed nothing characteristic histologically.

Owing to two attacks of dyspnea, one of which was nearly fatal, it was decided to resort to intensive x ray treatment without further delay. The dosage employed was ninety kw., five ma., seven minutes, at eight inches skin target distance, with a four mm. aluminum screen. After the whole area had been covered from the front the back was given a single exposure. There were no more attacks of asphyxia after the first treatment. After three treatments a radiograph showed the area of density to be about five cm. narrower, and distinctly less dense, than before the application of the rays. The findings by percussion agreed with this. When last seen on April 21st, the boy had gained seven pounds, had rosy cheeks, and abundant energy, and his white blood count which had been 11,000 to 13,000 had fallen to 8,000. The distended veins over the left chest had disappeared during his stay in the hospital, and the two sides of his chest were not equal. The röntgenographic findings were now practically normal. In the writer's opinion this was Hodgkin's disease or lymphosarcoma. He could not, however, definitely exclude a very large thymus hyperplastic gland, though if this had been present the conspicuous venous plexus should have been observed during his previous stay in the hospital, even if dullness were missed. Again, the thymus may have been sarcomatous.

Prognosis and Treatment of Tuberculosis in Infancy and Childhood.—Dr. ROWLAND GODFREY FREEMAN, of New York, stated that it was characteristic of tuberculosis in early life that it might cause considerable polynuclear with little leucocytosis or increased polynuclear count. There was very little emaciation and the lesion was more likely to be in the lower lobes of the lung than in the apices. The results obtained in the cases reported, Dr. Freeman believed, were due to the following curative agent, presented in the order of their comparative value:

1. Fresh out of door moving air, cold if possible. The value of this agent was generally conceded but too few cases were kept in this sort of air twenty-four hours each day.
2. Heliotherapy. This was a valuable agent in tuberculosis of the lungs in children in this country. In a limited experience Dr. Freeman had seen no bad results from its use. In visiting Rollier's sanitarium at Leysin, Switzerland, last summer, Dr. Freeman learned that they considered it a rather dangerous agent in lung tuberculosis. They used it but thought it should be employed with caution.
3. Codliver oil. This was a useful agent if it was well tolerated, as was usually the case.
4. A full diet was essential and complete rest was necessary for a long period.

Tuberculosis in infancy, which was localized, might be cured by prompt interference. If, however, it had involved the lungs, it rapidly became a generalized tuberculosis and gave an absolutely bad prognosis. Tuberculosis in either infancy or early childhood, whether rapidly progressive or slow in its progress, caused comparatively little emaciation. If an infant or young child with a chronic lung condition emaciated rapidly, the probability was the condition was not tuberculosis.

The Dose of Diphtheria Antitoxin: An Analysis of the Records of the South Department.—Dr. EDWIN H. PLACE, of Boston, declared that the effective dose of antitoxin must be determined chiefly by the results actually obtained in practice rather than by *a priori* facts from animal experiment. The striking influence of antitoxin on the mortality from diphtheria was so evident from statistics throughout the world as not to require citing here. In the South Department of the Boston City Hospital, the drop from an average of about forty per cent. to about fifteen per cent. in 1895 occurred with a dose of about 1,500 to 2,000 units. It thus was evident that doses now considered relatively small would effectively control a large percentage of cases and it soon became evident that late in the disease no dose was effective. It was possible that between these two groups there might be cases, probably few, in which the damage had not been unalterable, though small doses would not have saved them; larger doses were used and a slow decline in the mortality curve was noted. It was to inquire whether this was due to earlier treatment, milder cases, or difference in age of patients, or to difference in size of doses, that groups of cases were studied at different times. In the first group, 1895-1896, the dose of antitoxin was customarily from 1,500 to 2,000. In this group the mortality was 8.8 per cent. In the second series, 1900-1901, the usual dose was 2,000 to 4,000 units, occasionally 8,000 at intervals of four, twenty-four, and seventy-two hours, or even several days, until clinical improvement. Doses as large as 110,000 units were occasionally given subcutaneously. Only thirty-five per cent. received a single dose. In the third series, the doses were much larger, varying from 4,000 to 100,000, averaging about 30,000 units, of which ninety-two per cent. received only one dose; sixty-two per cent. were treated intravenously.

Whether increased dose or intravenous route played the more important part it was impossible to say, as no group of small intravenous doses was available in this clinic. In nearly all the severe cases for the past five years intravenous injections had been given, but no fall in the mortality curve had occurred; in fact, the mortality had increased somewhat so that other factors, it seemed, were more important. In the wards the estimate of the amount of antitoxin to be administered was made on the severity, the extent and especially the rapidity of development of the local inflammation. The general scheme of doses had been: Mild cases, 2,000 to 5,000; moderate, 10,000 to 30,000; severe, 30,000 to 100,000. No appreciable harm had been observed from these larger doses. These statistics again demonstrated that the time of treatment superseded all other factors in the mortality. This fact reiterated again and again, was not acted upon in actual practice as often as it should be. It was not a bad dictum that any inflammation of the mucous membrane should be treated as diphtheria unless proved clinically otherwise. In such a plan antitoxin should be given at once, unless the physician was sure that no harm could result from diphtheria with delay. The fear of anaphylaxis was much greater than fact justified and the fear of diphtheria poisoning was tremendously less. The figures presented in this paper showed: 1, that doses of 2,000 to 5,000 units were inadequate in diphtheria treatment, even if repeated at intervals; 2, that intravenous antitoxin in doses averaging 30,000 might save lives that would be lost with less adequate treatment; 3, that no doses of antitoxin were likely to reduce the mortality of diphtheria as a whole unless the delay in administration could be eliminated.

The Size of the Sella Turcica in Relation to Body Measurements.—Dr. Lawrence T. Royster and Nathaniel F. Rodman, of Norfolk, Va., presented this study, based on the tabulated records of four hundred children divided into groups as follows: Under two years of age; from two to five years; from five to nine years; from nine to sixteen years. There were fifty males and fifty females in each group. From the data collected it seemed fair to draw the following deductions: 1. A base of comparison of measurements had been established. 2. The torsa was of much greater length than the lower extremities in young children and the point of half the height gradually reached the upper border of the symphysis much earlier than had been suposed. 3. The fat pads in the upper pelvic girdle and over the sacral triangle were normal in infants and young children and were present in the majority of cases during older childhood, but began to disappear about the seventh year. They were to be considered as suggestive of dyspituitary dysfunction only when pronounced. 4. From infancy to the fifteenth years the average measurements of the sella turcica showed steady increase in size, amounting approximately to fifty per cent., but the interclinoid space did not increase in proportion to the other measurements of the sella, but on the other hand remained practically constant. 5. There was no definite relation between the size of the sella and the interclinoid space as measured on the flat plate and normal overweight or underweight children. 7. There was no definite relation between the size of the sella or interclinoid space as measured on the flat plate and the point of half the height or the height to span ration. 8. The relation of span to height remained practically constant throughout childhood. 9. The size of the sella as measured on the flat plate was probably a very inaccurate guide to the function of the pituitary. 10. In taking a radiograph of the sella distortions and shadows might occur which caused erroneous interpretation, due to the angle of either plane of the skull in relation to the target. These divergences might cause accentuation of the optic foramen, suggesting diverticula and the shadow of the outer angle of the lesser wing of the sphenoid might cause a distorted shadow of the interior clinoid process.

A Study of the Shadows in the Thorax of the Newly Born.—Dr. L. R. DeBuys and Dr. E. C. Samuels, of New Orleans, presented this study of fifty-two newborn infants, and included careful physical examinations and accurate measurements of all the cases examined which were consecutive and were not selected. Every baby was radiographed within the first forty-eight hours after birth, with the exception of a premature infant which was not radiographed until it weighed three pounds fourteen ounces. In none of these cases was there a heart murmur and in none was there any clinical evidence of enlarged thymus. In no instance was there the slightest evidence of inconvenience to the patient nor of interference in his normal progress following the making of the radiograph. The types of hearts as determined by the shadows were as follows: Globular, twenty-one; adult type, seven; drop heart, five; nutmeg, three; square, two; round, one; unusual, one; unclassified, ten.

The study was summarized as follows: 1. Heart shadows vary in shape, size, and position. 2. These variations occur with no relation to the size of the infant. 3. The heart shadows may be grouped in several types according to shape. 4. The variations in size and position occur in each of these types. 5. There is no constant relation between the heart shadow and the shadow of the thymus. 6. The shadow of the thymus is not necessarily influenced by the position of the heart. 7. The shadow of the thymus varies in its size and position independent of the heart shadow and with no relation to the size of the infant. 8. The variations in the shadows of the heart and of the thymus can exist without clinical manifestations of disease.

Cerebrocerebellar Diplegia—Atonic Type.—Dr. T. C. Hemplemann, of St. Louis, reported two cases of this condition, one with complete autopsy findings. The most striking thing about the brain in this case was the distinct asymmetry between the two cerebral hemispheres and the two lobes of the cerebellum which corresponded to a similar asymmetry of the cranial bones. The left half of the cerebellum was much thinner and smaller than the right, and the bloodvessels on the left side were considerably smaller than those of the opposite side. Sections were taken from the cortex at five levels, as well as from areas deeper in the cerebral substance, including the lateral ventricles and choroid, and also through the internal capsule, medulla, and right and left lobes of the cerebellum. In none of these sections were degenerative changes or sclerosis found. The same was true of sections of the cord taken at four levels. The asymmetry then was due to developmental defect.

The Nitrogen Metabolism in Some Conditions of Constitutional Diathesis.—Dr. Frederic W. Schultz, of Minneapolis, recalled that at a previous meeting of the society he had attempted to establish a series of normals for nonprotein nitrogen in blood of infants and older children. This work had been followed up by an extensive investigation of a large series of cases showing various pathological manifestations and conditions. The results showed that the nonprotein metabolism in all these conditions remained normal or nearly so, except in those cases which showed marked involvement of kidney function or were accompanied by marked febrile manifestations.

The method of blood analysis used was that of Folin and Wu. Blood sugar determinations were also made on all the material. A part of the material studied concerns a series of cases in which the organism showed some pronounced manifestation or phase of constitutional diathesis. As regards their metabolism, these individuals sometimes reacted somewhat differently from the normal. There were in all 112 cases, of which thirty-nine showed severe asthma, thirty-five were of the neuroarthritic type, seventeen had repeated attacks of cyclic vomiting. The remaining four cases showed pronounced evidence of spasmophilia. An effort was made to select only extreme types, so that there would be no doubt as to the presence of the condition, and any effect it might have on tissue metabolism. The results showed a higher output of the total nonprotein nitrogen in the asthma and exudative diathesis cases.

Abstracts from Current Literature

PEDIATRICS

Use of Lactic Acid Milk (Whole Buttermilk) in Infant Feeding Over Long Periods.—Borden S. Veeder (*Medical Clinics of North America,* July, 1922) has maintained a series of twenty-five to thirty cases of socalled difficult feeding on acid milk continuously for four to eight or even ten months. Nearly all children will take it and none tire of it. It produces not only a remarkable and steady gain in weight but also a splendid physical development. In addition to the lactic acid milk, codliver oil and fresh fruit juices are also given daily. Between the fifth and sixth months farina or cream of wheat is added and four to six weeks later a green vegetable. Culturally soured milks are just as good as the home made sour milk. A quart of fresh milk is boiled hard for several minutes and cooled rapidly, poured into a boiled glass jar, and the culture from a laboratory is added. The milk is allowed to stand at room temperature for several hours and then beaten up. On the next day three to four ounces of the milk of the previous day is added in place of the culture. Corn syrup or dextromaltose is used as the carbohydrate. The indications for the use of this milk are: 1. A baby over two months of age, who has been off the breast for two or more weeks, but who is not only three to four pounds under average weight for its age, but markedly undernourished and marantic. 2. A baby doing well on the breast or a complemental feeding, but which will not adjust in three weeks to a sweet milk mixture after breast feeding has been stopped. The acid milk mixture should be used more frequently in such cases than it has in the past.

Infantile Acute Endocarditis.—E. F. Skinner (*Lancet,* June 10, 1922) reports a very rare case of acute endocarditis in an infant four months old. An intractable eczema was the only reason for seeking medical attention, as aside from this eczema the child appeared remarkably well. About fourteen hours after admission to the hospital, the child was found dead in bed, but the cause of the death was not ascertainable. The necropsy showed nothing abnormal except the lungs and heart. The lungs showed subpleural hemorrhages. The heart appeared normal, but the tricuspid valve was less smooth than normal and the mitral valve was gravely involved, the free edges and the auricular surfaces of the flaps being covered with soft vegetations, not large, quite recent and extremely friable; there were no congenital defects and the coronary arteries were patent. There were no clinical signs of cerebral or pulmonary disturbances and no pathological features. The cause of death was probably the onset of ventricular fibrilliation following an embolus in a coronary artery sufficiently small to have passed beyond the openings without giving any signs apparent to the naked eye. The author believes this case to be a very rare form of the required disease and not fetal in character for the following reasons: 1, there was no history of rheumatism in the mother or any disease transmissible through the placenta; 2, the left side of the heart was affected more than the right; and, 3, there were no congenital cardiac defects.

Studies in Butter Flour Nutrition.—H. Ernberg (*Acta Paedriatica,* December 16, 1922) used butter flour diet as prepared by Czerny and Kleinschmidt in doses not exceeding two hundred grams to the kilo of body weight in 375 cases. The result was satisfying, particularly in the cases of debilitated and undernourished infants in the very first months of life. Good results have also been obtained in numerous instances in the treatment of older infants. Its use is contraindicated in cases of diarrhea, grave chronic nutritional disorders, or in cases with a marked tendency to diarrheal and weight reducing reactions to parenteral infections. It does not seem to have any particular advantage in the treatment of rachitis. This diet should only be followed under the direction of a physician.

Edema in Childhood.—H. C. Cameron (*Clinical Journal,* July 5, 1922) says that angioneurotic edema is probably more common in childhood than at any other period. There is a marked family predisposition, and the disease seems to be especially common among Jews. Children who suffer in this way are usually quick, excitable, of a highly nervous temperament, and an attack may be occasioned by an emotional outbreak. The edema usually occurs in circumscribed patches, common situations are the eyelids, lips, hands and fingers, though sometimes large joints are affected. Giant urticaria may occur with or between the attacks. More serious are cases in which one or another part of the viscera is involved; a serious exudate into the bowel wall may produce symptoms of intestinal obstruction, into the larynx may cause suffocation. When the attacks are clearly associated with excessive emotional display and extreme nervousness, attention must be paid to the management and the personal influences which surround the child. Calcium bromide or calcium lactate, four or five grains, or liquor trinitrini, one minim, may be tried. If the attacks appear to follow upon the ingestion of any particular food, the suspicion can be confirmed by noting the reaction of the patient's skin to solutions of the suspected protein. The test is carried out as for a Von Pirquet tuberculin test. If the test is positive an attempt may be made to desensitize by graduated injections.

Treatment of Diabetes Mellitus in Childhood.—N. Johannson (*Acta Paedriatica,* December 16, 1922) having used the Joslin starvation treatment for the diabetes mellitus cases in the Crown Princess Lovisa's Hospital for Sick Children in Stockholm, formulates his opinion on the result of the treatment as follows: The system was carried out on fairly rigid lines, thus facilitating the accomplishment of its object, allowing us to get rid of sugar and ketone elements more rapidly than would otherwise be possible, and above all enables us to apply ourselves much more energetically and successfully than was possible with the older methods to the struggle against acidosis. This establishes a tolerance regarding the individual foodstuffs, which appears to be of remarkable and lasting duration. The dietary during the course of the cure quickly becomes extremely varied, in contrast to what was the case in the past with regard to the diabetic diet. The characteristic of the treatment by starvation diet is that it often leads to a very obvious loss of weight, which, however, is not considered dangerous to the general health or to tolerance. On the contrary the latter, as a rule, also stands the strain in the shape of a diet so generous that it permits the loss of weight being repaired and even of the weight being increased. Whether the otherwise grave prognosis in diabetes in childhood can ultimately be influenced to any extent by Joslin's method, is a question which our experience up to the present does not permit to answer. It is, however, not inconceivable that this may prove to be the case. It undoubtedly indicates a certain improvement, since it is attended by a relatively endurable existence for the patient over a considerable period of time, this being the obvious result of the privations she is called upon to endure and in this way her interest in life is increased and her ambition aroused to carry out the doctor's instructions in every particular, a point of view to which a certain value may be accorded, at any rate in the case of older children.

The Red Corpuscles and Their Variations.—E. J. Rud (*Acta Medica Scandinavica,* November 29, 1922) performed a series of experiments with the object of ascertaining the average, maximum, and minimum number of red corpuscles in healthy individuals. He examined sixty-nine adults of all ages and forty-nine children with the following results: In male adults, the average number of red corpuscles was 5,330,000 to the c. c., the maximum 5,900,000, and the minimum 4,370,000. In female adults, the average was 4,850,000 to the c. c., the maximum 5,390,000, and the minimum 4,300,000. Subjects of advanced age showed a slightly lower average than the younger subjects. In the children, the newborn showed the highest average: 5,680,000. Maximum 6,590,000, and minimum 4,470,000. Nursing infants: Average 5,110,000; maximum 5,930,000, and minimum 4,270,000. Infants between one and fourteen years of age: Average 4,960,000; maximum 5,590,000, and minimum 4,580,000. Sex had no appreciable influence on the number of red corpuscles in children.

Experimental Rickets.—E. V. McCollum, Nina Simmonds, J. Ernestine Becker, and P. G. Shipley (*Journal of Biological Chemistry,* August, 1922) in a series of studies found that codliver oil oxidized for twelve to twenty hours does not cure xerophthalmia in rats, but does cause the deposition of calcium in the bones of young rats suffering from rickets. Other fats, such as cocoanut oil, shark liver oil, burbot liver oil, and certain vegetable fats, as cottonseed oil, maize oil, sesame oil, and olive oil, were also studied. The evidence described here demonstrates that the power of certain fats to cause the healing of rickets depends on the presence in them of a substance which is distinct from fat soluble A. The experiments show the presence of a fourth vitamine, whose specific property appears to be the regulation of the metabolism of the bones.

Alfred F. Hess, Lester J. Unger, and Joseph M. Steiner (*Journal of Experimental Medicine,* October, 1922) subjected animals on a rickets producing diet to irradiation with röntgen rays, in all of which, in spite of this treatment, rickets developed. This result was quite contrary to that obtained when the mercury vapor or the carbon arc lamp was used. Rats on a diet containing phosphate in an amount adequate to prevent rickets did not become rachitic when exposed to massive doses of röntgen rays of an intensity sufficient to produce marked destruction of the blood forming cells of the marrow. These authors, working in conjunction with Alwin M. Pappenheimer, were able to protect young rats on a diet low in phosphorus from the development of rickets by irradiations with sunlight for about fifteen minutes daily, though during the winter months this degree of light was insufficient. The rays from a mercury vapor lamp, and also from a carbon arc lamp, were likewise efficient protective agents. Moderate variations in temperature do not alter the efficiency of the light rays.

Bladder Diverticula in Children.—A. Hyman (*Surgery, Gynecology, and Obstetrics,* January, 1923) concludes that vesical diverticula are rare findings in childhood, not more than thirty being found in a review of over six hundred cases. Diagnosis of this condition in children should present no difficulties. Little value can be placed on the history. Physical examination of the abdomen is of considerable importance. A chronically distended bladder, especially asymmetrical in outline, should make one suspicious of a diverticulum. The cystoscope and cystogram are absolutely essential in making a correct diagnosis. Of the two, the cystogram will be found more valuable. No evidences of obstruction, either vesical or urethral, were found in the three cases reported in this article. All three diverticula were in immediate proximity to the ureter; in one, the ureter opened into the sac and as a result, the ureters were compromised to such a degree as to cause obliteration of the lumen, with resultant dilatation. Division of ureter with reimplantation was performed in all three cases, with recovery of patients. Undoubtedly there will be an increase in the number of cases reported as soon as cystoscopy in children becomes more of a routine procedure. The presence of diverticula in patients so young, without evidences of any obstruction, leads one to conclude that they were congenital and that in all probability many of the diverticula in adults have also a similar origin.

Nasal Obstruction in Infants During the First Year of Life.—J. Arnold Jones (*Lancet,* August 12, 1922) enumerates the following causes of nasal obstruction during the first year of life: 1, Congenital occlusion of the nostrils, a, of the anterior nares through a congenital web of skin at the junction of the vestibule with the nasal chamber proper, and b, of the posterior nares, where a diaphragm consisting of bone, or partly of bone and partly of membrane, may partially or totally obstruct one or both choanæ; 2, the temporary presence of mucous secretion in the nose and engorgement of the nasal mucous membrance, during the early days of life before mouth breathing is established; 3, congenital syphilis; 4, mongolism, and 5, adenoids—the most common cause of all. The symptoms are: 1, Inability to suckle efficiently; 2, snoring when asleep and frequent suffocative attacks; 3, persistent cough; 4, nasal discharge; 5, convulsions; 6, otorrhea. The first two symptoms establish the diagnosis. The treatment is elimination of the cause.

Adolescent Rickets.—P. Lewin (*Surgery, Gynecology and Obstetrics*) asserts that it is a very interesting fact that these deformities either make their appearance, or, if present, grow markedly worse, coincident with adolescence. During this period increased demands are made on the organism, and if at that time the general metabolism and especially bone metabolism is disturbed, deformities are prone to occur. It is probable that a combination of bone softening and heavy lifting or carrying causes some cases. Others are due to relaxation of muscles and ligaments, and in this type infections may be a causative factor. Certain definite factors occurring at a certain definite "cycleogical" time. These factors are: 1, the growing period for that individual; 2, athletic overindulgence, as seen in the high school boy; 3, physical overwork, such as carrying heavy loads as in the case of the grocery boy, or the young girl doing domestic work which is too strenuous for her; 4, general food deficiency; 5, particular food deficiency; 6, stimulated endocrine activity; 7, suppressed endocrine activity; 8, disturbed endocrine activity, i. e., abnormal chemical secretions. It is Lewin's belief that the whole question is one of bone metabolism and especially calcium metabolism due to the above mentioned factors, and the immediate cause of deformity is a disproportion between the carrying power of the bones and the load they are forced to carry. He believes that corrective measures should be instituted and that operation is not attended by unusual risk.

Calcium and Phosphorus Metabolism in Childhood.—H. C. Sherman and Edith Hawley (*Journal of Biological Chemistry*, August, 1922) determined the complete balance of intake and output of calcium (and in most cases also of phosphorus) in four progressive series of experiments on twenty-one children between the ages of three and fourteen years. As a result of this investigation the following points are brought out: On an ordinary mixed diet containing daily 750 gm. of milk and furnishing a total of 0.74 to 1.02 gm. of calcium a day, these children stored 0.15 to 0.62 gm. of calcium daily, the amount being approximately proportional to the size of the child, and averaging 0.01 gm. of calcium to the kilo of body weight a day. An increase of the daily milk allowance to 1,000 gm. increased the storage of calcium. The optimum storage of calcium seems to occur when the diet contains a quart of milk a day for each child, and the necessity of maintaining this level of milk intake up to at least the age of twelve to fourteen years is emphasized. Experiments were made in which vegetables replaced about half of the milk in a course of the calcium. The children did not seem to utilize the calcium of the vegetables as efficiently as that of the milk, and the balances were also more variable and less favorable. In general, the conditions influencing the storage of calcium tended to influence that of potassium in the same direction. The requirements of children of three to thirteen years of an intake of a gram of calcium a day to induce optimum storage of this element has an important bearing on standards for calcium in family dietaries. In groups of people where growing children are to be fed perhaps one gram of calcium or more a day for each person should form part of the diet.

A Comparison Between the Medicinal Dietetic Treatment and Light Treatment in Rachitis.—I. Jundell (*Acta Paedriatica*, December 16, 1922) finds that the medicinal dietetic treatment and the light treatment have about the same considerable healing effect on the rachitis. The judgment will be about the same with regard to the clinical picture as well as to the result of the röntgen examinations. The combined medicinal, dietetic and light treatments do not lead to appreciably quicker results than the treatment with one or the other of these methods. The medicinal dietetic treatment is especially indicated, first, in all the numerous cases where the child is manifestly overfed, and, second, when the outward circumstances make the arranging of light treatment impossible, and the child's state of nutrition does not contraindicate a relative inanition for some time. The method of light treatment is specially indicated, first, in those cases where the state of nutrition is such that the child might be injured by a period of relative inanition, and, secondly, in those cases where the child suffers from an illness of a kind or in a stage which makes it desirable to keep the child in a specially good state of nutrition. The light treatment exercises its favorable effect with ordinary and even ample diet. Twenty-one case reports are given in detail.

The Newborn During the War.—Michael David (*Zentralblatt für Gynäkologie*, May 20, 1922) on reviewing the statistics, found that the number of miscarriages and the number of stillbirths did not increase during the war; that the number of male children were not increased; that the mortality of the newborn children was not increased for the first few days of life; that the body measurements of the newborn showed an average decrease during the war, which decrease was still more marked during the last three years of the war, with a more pronounced decrease in the number of males; the greatest decrease was found in the weight (3.0 to 3.75 per cent.), the next in length (2.5 to 3.2 per cent), and the least in the circumference of the head (0.9 per cent.); the decrease in the average measurements was not produced by the shortening of the period of pregnancy to 273 days. Unquestionably, deficient nourishment was the most effective factor.

The Nervous Complex in Infantile Intoxications.—G. Bessau, S. Rosenbaum, and B. Leichtentritt (*Monatsschrift für Kinderheilkunde*, August, 1922) conclude that: 1. The nervous complex of intoxications consists of coma, deep respiration, catalepticlike conditions, convulsions, vomiting, and symptoms of disturbances of the vegetative nervous system (fever and subnormal temperature). 2. The possibility of an abnormal permeability of the epithelium of the corneum cannot be excluded in the presence of a positive result with the Löwi reaction. 3. Disturbances of temperature and the symptoms of the nervous complex are most closely related; the disturbance of temperature is a less characteristic but more delicate symptom, but both phenomena are probably the expression of a central disorder. 4. Starvation does not cause a recession of the nervous complex. 5. The administration of food, *per se*, seems to be harmless and only in an indirect way can it act injuriously through the production of diarrhea or vomiting, which, in turn, are the causes of an exsiccation of the organism. 6. The increased permeability of the gastrointestinal canal is not an absolutely necessary prerequisite for the development of the nervous complex and the increased permeability certainly does not in itself lead to the appearance of the nervous complex. 7. With a material of alimentary intoxication, it is impossible to decide definitely whether or not the infection of the upper segments of the intestine with colon bacilli is a prerequisite for the occurrence of the nervous complex; to decide this, it is necessary to include numerous experiments with infections which show the symptoms of alimentary intoxication. 8. In every case in which the nervous complex occurs there are usually signs of extreme desiccation and an oliguria or anuric condition. 9. The anuria is not the result of an anatomical or functional renal disease, but it is due to extrarenal factors. 10. The residual nitrogen values in the fully developed nervous complex vary extremely in different cases, values between 17.1 and 176.4 having been observed; there is no relationship between the residual nitrogen content and the nervous complex.

Time of Occurrence of Chorea.—R. Nordgren (*Acta Paedriatica,* December 16, 1922), in a study of the chorea cases in the Samaritan Hospital, Sweden, from 1909, found that chorea occurs more frequently in certain epochs than in others. An elevation in the frequency of rheumatoid affections coincides with or immediately precedes an increase in chorea cases. This would point to the rheumatoid affections as etiologically connected with chorea. In 343 cases of chorea, 193 had suffered from rheumatism. Chorea appears simultaneously or directly after other infectious diseases, such as scarlatina, tonsillitis, just as endocarditis (acute) usually appears after other infectious diseases than acute polyarthritis, although the latter is the most frequent cause. Psychic factors of an exciting nature may in some cases act as a contributing factor. Girls are more often affected with chorea than boys. In the author's 343 cases, 218 were girls. Chorea appears most often between the ages of five and fifteen years. Before the fourth year it is comparatively rare although it has been observed in infants of three years of age. The following shows the age incidence: Three to six years, boys nine, girls twenty-nine; six to eight years, boys thirty-one, girls thirty-eight; eight to ten years, boys forty-three, girls seventy-seven; ten to twelve years, boys thirty-three, girls fifty-one; twelve to fifteen years, boys nine, girls twenty-three.

Studies Upon Experimental Measles.—Charles W. Duval and Rigney D'Aunoy (*Journal of Experimental Medicine,* August, 1922) inoculated defibrinated human blood from a case of measles at the stage of temperature height into rabbits, with the production of a specific reaction analogous in all essential features to that of the human infection. Following a definite incubation period of from two to five days the animals showed a temperature rise concomitant with which there was a diminution in the total number of circulating leucocytes. The most striking objective signs were coryza, conjunctival injection, enanthemata and exanthemata. The mucous membrane lesions were similar in their physical appearance to the socalled Koplik spots seen in man. Repeated passage of the virus of measles through the rabbit seemed to increase its virulence. In the animals dying apparently as a result of the specific virus grave nephritic changes were evident. The authors also produced in guineapigs and rabbits as a result of the introduction into their circulatory and respiratory systems of filtered nasopharyngeal washings from cases of human measles, reactions similar to those obtained by the injection of blood from measles cases. The specific reaction in the rabbit is characterized by enanthem, exanthem, and pyrexial disturbances, and in the guineapig by pyrexia, marked leucopenia, and in the fatal cases grave nephritis. The authors believe that experimental measles is primarily a blood infection, the mucous membrane lesions being secondary.

Operation as Part of the Conservative Treatment of Pott's Caries.—W. I. de C. Wheeler (*Practitioner,* November, 1922) maintains that the conservative treatment in children is best without operation, but that all adults who cannot or will not endure prolonged treatment should, in the absence of special contraindications, be given the benefit of operation. The additional fixation obtained by a bone graft often determines cure in the patient who has not responded to nonoperative treatment. More rapid recovery frequently follows operation in cases of paraplegia. An active primary tuberculous lesion is not *per se* a contraindication to operation. Prudence dictates three months postoperative treatment in bed and rest should be advised for twelve months.

Experimental Mumps Meningitis. — Martha Wollstein (*Journal of Experimental Medicine,* December, 1921), by injecting sterile mouth filtrates from early mumps cases into the subarachnoid space of cats, caused signs of meningeal irritation, consisting of increase in the amount of cerebrospinal fluid, with an abnormal content of cells and globulin, increased intrameningeal pressure and consequent symptoms of irritability, ocular irregularity, prostration, and fever These meningeal lesions were then transmissible from one cat to another by using the cerebrospinal fluid. The latter did not contain bacteria at any time which grow with the ordinary culture methods.

Etiology of Scarlet Fever.—R. W. Pryer (*Journal of Laboratory and Clinical Medicine,* July, 1921) isolated a large coccus shaped organism from scarlet fever patients. In size it somewhat resembled a yeast. It has not yet been found in other conditions. Culturally the growth is strictly aerobic; the optimum temperature is 30° to 40°; it is spore producing, and grows on very alkaline media and on a medium deficient in meat products. The spores are resistant to heat, withstand at least two hours' boiling, but are usually killed by a temperature of 110° in the autoclave.

Primary Malignant Growths of the Liver in Infants.—C. B. Dansie (*Lancet,* July 29, 1922) reports a very rare case and reviews twenty-three cases found in the literature of primary malignant growths of the liver in infants up to two and a half years of age. Most of the cases occurred in the first six months of life. The author's case was one of a duct carcinoma, which no doubt originated in connection with the bile ducts as the cells composing it did not resemble the liver parenchyma, nor was the growth of a green color, which indicated that the cells of the tumor were functionating.

NEW YORK, WEDNESDAY, MARCH 7, 1923

CARDIOVASCULAR DISEASES

The Heart in Myxedema.—Sven Zandrén (*Zentralblatt für Herz- und Gefässkrankheiten,* July, 1922) finds that the characteristic symptoms referable to the heart in myxedema are the following: 1. Dilatation of the heart in both directions, no signs of a valvular defect or of myocarditis and a normal or subnormal blood pressure. 2. Subjective symptoms of dyspnea and palpitation may exist for a long time unchanged. Gradually there develop edemas, localized mainly in the lower parts of the body which reach enormous dimensions; the skin becomes thickened, it cannot be lifted in folds and it is cold and scaly. 3. There is a disproportion between the objective findings in the heart and the pronounced edema with the severe subjective symptoms of insufficiency. 4. There is no or only a slight therapeutic effect noticeable from the usual treatment of the heart, but an excellent result is seen from the administration of thyroid gland preparations. 5. In many cases it is possible to demonstrate slight somatic or psychic symptoms of hypothyroidism.

Digitalis in Cardiac Disease.—Henry A. Christian (*Boston Medical and Surgical Journal,* July 13, 1922) states that after a fair trial of various available digitalis preparations he is convinced that none are superior to digitalis in its simplest form, the leaves powdered and mixed with a sticky vehicle so as to make a pill. He goes on to say: Digitalis may be given in a single massive dose, or in a modified massive dose method, or in regularly repeated small doses. Any of these methods is effective. The chief difference lies in the length of time needed to produce a result. For the average cardiac case there is no real preference. In a few very severe cases the modified massive dose method is better. Occasionally the single massive dose may be lifesaving. When all is done and said, digitalis therapy is very simple. Just give enough of a potent leaf, prepared in any way, by any accepted method of administration, and the result is most satisfactory in almost every case.

Disorders of the Heart Mechanism.—J. P. Munroe (*Southern Medicine and Surgery,* July, 1922) presents the following summary and suggestions for treatment. 1. Sinus arrhythmia: found chiefly in children; disappears on exercise; calls for no treatment. 2. Premature contractions: lessen or disappear when the heart is accelerated by emotion, fever or exercise; drugs not indicated as a rule; multiple premature contractions indicate myocardial insufficiency, call for rest and attention to the gastrointestinal tract and any systemic or focal infections; bromides are sometimes useful; digitalis when the heart muscle is exhausted. 3. Paroxysmal tachycardia: rapid rate abrupt in onset and termination, not affected by position or exercise, often cut short by pressure on vagal nerve; neuropathic cause should be sought and treated; digitalis administered only when heart muscle shows signs of exhaustion. 4. Auricular flutter: rare; may be suspected when very rapid, regular pulse is suddenly halved; treatment, digitalis. 5. Auricular fibrillation: pulse irregular in rate, rhythm, and volume, disordered ventricular action, heart usually beats faster than the pulse; exercise increases the irregularity. Treatment, digitalis or one of its substitutes. Atropine, belladonna and hyoscyamus to be avoided. 6. Heart block: most often with a pulse rate of fifty or less; sudden drop while taking digitalis or in convalescence from acute diseases is suggestive. No treatment needed as a rule; digitalis not to be used; epinephrine or atropine should be given in severe cases. 7. Alternation of the heart: easily recognized by the use of blood pressure apparatus or, in cases of halved pulse by comparing radial pulse with ventricular beat. With hypertension and cardiosclerosis it indicates serious heart weakness and a fatal issue not far off; with normal blood pressure it may be relieved by digitalis.

Treatment of Cardiac Failure during Pregnancy.—H. E. B. Pardee (*American Journal of Obstetrics and Gynecology,* June, 1922) asserts that the important feature in a patient with heart disease during pregnancy is the degree of cardiac failure; if this is slight the disease is of little importance. Even the first attack of severe decompensation can usually be recovered from with proper treatment, unless the attack occurs during labor. Abdominal section is the operation of choice in the latter emergency, provided a low forceps delivery cannot be done. Ether preceded by chloroform is preferable as an anesthetic for these patients to gas oxygen. Oxygen inhalations from a mask are helpful to clear up a persistent cyanosis. Without severe cardiac failure or after recovery from it, most patients can be carried through to term or to an induced labor during the eighth month. During labor, one should watch for a pulse rate exceeding ninety-five or respiration exceeding twenty-five a minute, precordial discomfort, dyspnea, and cough, and should not allow these signs to become pronounced before putting an end to labor. In lesser grades of heart failure during pregnancy, the patient must rest enough to spare the heart from overstrain; this may not, however, necessitate rest in bed for more than a short time. Digitalis should be given in doses sufficient to insure an effect. With this treatment it will be possible to diminish the present mortality of about twenty-five per cent. in severe cases and ten per cent. for all cases.

Vitamine C as Vegetable and Animal Tyrosin and Tyrosinase, Jointly the Homologues of Adrenalin Tests and Food Values*

By CHARLES E. de M. SAJOUS, M.D., LL.D., Sc.D.,
Philadelphia,
Professor of Applied Endocrinology, University of Pennsylvania Graduate Medical School.

The subject which President Anders requested me to consider at this meeting, the vitamines, was welcome for several reasons. First among these is the fact that the endocrine glands are increasingly being recognized as participants in the pathology of deficiency diseases, which means additional support of my contention of two decades ago that the internal secretions were of paramount importance in the genesis of disorders other than the pure endocrinopathies. A second source of gratification is that it affords another opportunity to urge that there is a true science of endocrinology distinct from the prevailing chaos so generally mistaken for it. A third reason is that it enables me to emphasize anew that researches in but one of the many branches of medical science cannot reveal the functions of the endocrine glands. This is shown by the failure of physiology to do so even during the sixty-three years elapsed since Claude Bernard initiated modern endocrinology and despite earnest physiological researches which, indeed, have yielded a vast array of invaluable data, though no actual function.[1] Finally, it permits me to add another link to the chain of evidence attesting to the supreme importance of certain endocrines in bodily functions. Those I have attributed to the adrenals, as we shall see presently, furnish at least a strong clue to the identity of one vitamine in both animal and plant life. The bearing of this statement may be gathered from the fact that Casimir Funk, in closing the second edition of his admirable book on the vitamines (1) recently issued, writes: "We must still await the investigator who, through tedious and patient work, will take the decisive step forward—the recognition of the exact nature of the vitamines."

A few high lights of the subject may prove helpful as a preamble. Beri beri or multiple neuritis had long been known by the Japanese to be in some way connected with a faulty diet, but Eykman, a Dutch physician, found in 1896 that while polished rice caused the disease in fowls, unhusked or red rice failed to do so. Vordeman then fed polished and unpolished rice to thousands of prisoners in Java and, as a result, urged the adoption of unpolished rice for State institutions. In 1909 Fraser and Stanton extracted from rice millings a substance which prevented and cured beri beri. Casimir Funk, of New York, then succeeded in 1911 in further concentrating this substance, and, considering as he did the basic group as an amine while desiring to emphasize its vital importance, called it "vitamine." Various substances other than rice millings are now known to contain the antiberiberi vitamine: yeast and germinating seeds particularly, then natural grains, nuts, certain vegetables, orange juice, milk, etc. This vitamine is generally known as the water soluble antineuritic vitamine B.

Equally important researches were conducted by our fellow member, Professor Osborne, with Professor Mendel, both of Yale, in 1912, who in experiments in rats covering a period of over a year, greatly advanced our knowledge of the food values of various proteins in their bearing on growth and normal health. This vitamine, which will be studied at length in another paper, was found to be present and soluble in certain fats and oils. E. V. McCollum, of Baltimore, independently reached similar conclusions in 1913. In addition to its influence on growth and general health, the fat soluble vitamine was found to influence profoundly the calcification of bone, as observed in rachitis and dental caries. It is known

*Read before the American Therapeutic Society, May 1, 1922, and by invitation before the Homeopathic Medical Society of the County of Philadelphia, October 12, 1922.

[1] This is the underlying cause of the present confusion in endocrinology. Without a knowledge of the functions of an organ, its symptomatology, pathology and therapeutics (including organotherapy) cannot be placed upon a sound foundation. I have long urged that a broad view of the subject, e.g., coordinated and synthetized evidence —facts only—from all branches of medical science, clinical and auxiliary, could alone solve so vast a problem. Hence the fact that the functions I attributed to the adrenals so deeply involved in the study of the vitamines have, as shown in the present paper, alone stood the test of time.

Copyright, 1923, by A. R. Elliott Publishing Company.

as the "antirachitic fat soluble vitamine A." Cod-liver oil is richest in this particular agent; next come butterfat, cream, eggfat and green vegetables.

Scorbutus, including the infantile type, the adult form of which disease has been the bugbear of soldiers and mariners for centuries, and which during the last war was very active particularly in Mesopotamia, Serbia and Russia, has long been recognized as a deficiency disease. It may be prevented by various citrus fruits, certain fresh vegetables, especially tomatoes, fresh beer, germinating seeds, etc., the vitamine of which has been termed "antiscorbutic water soluble C." As scorbutus will form the basis of this paper, additional details will be considered later in their logical sequence.

Briefly, the dietary constituents which formerly were thought to be supplied by proteins, fats, carbohydrates and mineral salts no longer suffice to explain many morbid phenomena witnessed. To do so we must now take into account the presence of some food principle or principles, the vitamines, which are capable, when administered in time, to check with comparative promptness, several deficiency disorders which otherwise would end in death. It is not for want of effort that the nature of the vitamines has not come to light. Indeed, Funk's treatise alone refers to nearly sixteen hundred papers and monographs on the subject. Does this not suggest the absence of some dominating factor in the study of the subject? This factor, as will now be submitted, appears to be concerned with a function I attributed to the adrenals now nearly two decades ago.

A FUNDAMENTAL FUNCTION INHIBITED IN VITAMINE DEFICIENCY.

The process of respiration, including tissue oxidation, even as now taught in medical schools, is known to have been defective ever since 1856, when Vulpian, followed by Paul Bert, Müller and other physiologists showed that the diffusion doctrine did not explain the complete disappearance of oxygen in the lungs of strangulated animals, nor oxygen tensions in the arterial blood exceeding greatly those in the air of the bronchial tract.[2] These and other discrepancies led Bohr, a Danish physiologist, to urge in 1891, that a substance having greater avidity for oxygen than the blood itself was necessary to explain the respiratory process. He was sustained by other physiologists, Haldane, Lorrain Smith, Harley and others. The identity of the substance needed, however, remained obscure.

In 1903 I (3) submitted after laboratory studies in lower forms, of the biochemistry of fluids connected with the respiratory process, besides the anatomical relations of respiratory organs, clinical observations, etc., and a comprehensive analytical study of the literature of the various branches of medical science, clinical and auxiliary, that the secretion of the adrenals carried on this important function. Since it was formulated this interpretation has been sustained by experimental and clinical data from so many directions that, if evidence means anything at all, it imposes its acceptance as an important function of the suprarenal medulla.

This evidence, to which several branches of medicine contribute, includes among other data the following effects found to be produced by adrenalin[3]: It facilitates the free circulation of air in the pulmonary air cells by causing dilatation of the bronchioles (4, 5, 6); it converts venous blood into arterial blood on exposure to the air and also transforms hemoglobin into oxyhemoglobin (7, 8, 9); it increases the intake of oxygen, the output of carbon dioxide, the volume of air breathed, the respiratory excursions of the lungs and the depth and rate of respiration (10, 11, 12, 13, 14, 15, 16). As to its systemic effects, and in keeping with its power to convert hemoglobin into oxyhemoglobin, adrenalin was found in the blood and red corpulcles (17, 18); it raises the temperature even in small doses (19, 20, 21); it accelerates metabolism (22); the temperature is raised to such a degree, when large sections of the adrenal substance are grafted, and, irrespective of any infection, as to cause death (23, 24, 25); it causes when in excess, as in malignant adrenal tumors and regardless of their histological structure, a febrile course irrespective of any fevercausing complications (26); adrenalin produces even in doses as small at 0.5 c. c., as observed in seventy-three experiments in endocrine patients, an increase in the basal metabolism rate (27); it causes an increase in the intake of oxygen and in the output of carbon dioxide before accelerating the metabolic rate (28); and it increases in appropriate doses the excretion of urea (29). Conversely, as is well known, removal of both adrenals reduces the intake of oxygen, the output of carbon dioxide, and causes dyspnea; it lowers also the temperature, the urea excretion (30), and finally, markedly reduces the basal metabolism rate (31).

The importance of this interpretation and the array of confirmatory data submitted—of which the foregoing represent but a fraction—are especially suggestive in view of Halliburton's statement in the last edition of his *Physiology* (1921) (32) that "knowledge of tissue respiration is so scanty that we can say but little about its pathological bearing."

THE BEARING OF TISSUE OXIDATION THROUGH THE ADRENALS UPON THE GENESIS OF SCORBUTUS.

Returning now to the relationship between the adrenals and the vitamines, it becomes possible to understand the purpose of Lieut. Col. R. McCarrison's question in his recent work on the Deficiency Diseases (33) in reference to the identity of adrenalin: "Is it a mere excretion, as suggested by Gley, or is it a powerful hormone concerned in the control of metabolic processes?" To this he answers, as a result of his studies, that "an intimate relationship exists between the adrenal glands and the metabolic processes of the animal organism." To this he would have added, had my writings been within his reach in India: "as Sajous showed in 1903 (3), and has repeatedly urged since."[4]

---

[2] C. R. Barnes (2), professor of plant physiology at the University of Chicago, having had occasion to "diligently examine" our "most thorough" textbooks of physiology, concluded that "the respiratory ratio has proved a veritable will-o'-the-wisp, leading investigators into a bog where their labors and their thinking were alike futile. For, as a sign of what is going on within, the respiratory quotient is absolutely valueless." In my opinion, the persistent great mortality of pulmonary and cardiovascular diseases and the lack of progress in many directions are mainly due to this fact.

[3] The term adrenalin is used here because the active principle of the adrenal medula was employed in practically all the experiments related.

[4] It should be remembered that while before I explained this process in 1903 "metabolism" was used as a random term by physiologists and others when referring to the adrenals, no one had explained it. Nor had any one established a connection between this organ and the respiratory process or tissue oxidation. The absence of this factor has also greatly hampered progress in our knowledge of metabolic diseases.

Another essential feature of McCarrison's researches is that "the functional perfection of the adrenal glands is dependent upon the balance of the food and upon the quality and quantity of its vitamines." To emphasize the importance of this fact in the process analyzed, I will again quote his words (34) in respect to scurvy: "1. A scorbutic diet causes depreciation in functional capacity of the adrenal glands in guineapigs. 2. The impairment of adrenal function occurs *before* clinical evidences of scurvy manifest themselves."[5] Another feature, the bearing of which will assert itself as we proceed, is that a scorbutic diet in guineapigs while causing "an increase in size and in weight of the adrenal glands" was found by McCarrison to cause "a marked diminution in the adrenalin content of these organs" . . . "less than half that present in healthy guineapigs."

In the light of the rôle of the adrenal secretion in tissue oxidation, all the biochemical phases of which may be produced by the experimental use of adrenalin, we have seen, a marked diminution of this principle should naturally entail atrophy or degeneration of the tissues at large including the various endocrines. I will quote as testimony an excerpt from Funk's (35) review of this phase of the question which applies to beri beri as well as to scurvy: "The first investigations in this direction were made by Funk and Douglas (36). The findings in pigeons showed that the thymus glands disappear; this was also noted by R. R. Williams and Crowell (37). The behavior of this gland in birds was then investigated further by McCarrison (38). Funk and Douglas made a histological investigation of pituitary, adrenals, ovary, testicle, kidney, liver, pancreas and spleen. In all these organs definite signs of degeneration were noted."

Applying these data to the pathogenesis of scorbutus in which the production of adrenalin is markedly inhibited, the feature to be borne in mind is that all tissues suffer not only from the effects of reduced oxidation, but also from deficiency of the specific hormones upon which their very structural integrity depends, the result in turn of the atrophic condition of the various endocrines. To give a few examples, the initial weakness, lassitude, fatigability, torpor, mental and physical, are typical signs of deficient tissue oxidation. The same cause, however, favors a trend toward tissue death, as illustrated by the fungous, purplish, ulcerated, gangrenous gums and the decaying teeth, and the general tissue disintegration. Another important factor in this connection is the vascular failure, due to deficient oxidation of the arterial muscularis and also of the sympathetic nervous system (which is penetrated by the adrenal oxidizing substances through its myoneural junctions). These effects by entailing relaxation of the arterioles, plus the abnormal fluidity of the blood, cause the familiar hemorrhages in all directions, including the subperiosteal tissues. The bones, moreover, suffer from deficient calcium metabolism owing to the thymic atrophy. The thyroid, likewise atrophied, fails to sustain systemic catabolism and also its important rôle in the antitoxic and bactericidal processes, now repeatedly confirmed, and in which trypsic enzymes take part. The pancreas, the source of the trypsinogen, being also atrophied, correspondingly reduces its participation in these defensive functions—carried on by the trypsic cytase (Metchnikoff), the "defensive digestive ferment" (Abderhalden), etc. The exposed tissues, the gums, stomach, intestines, etc., thus become the prey of pathogenic bacteria, greatly complicating the morbid process. Hence the degenerative changes in these organs, the multiplicity of gastrointestinal disorders observed and also the frequency of pneumonia in these cases.

On the whole, it seems evident that while it is the marked deficiency of adrenalin which underlies the genesis of scorbutus as a deficiency disease, it is because this adrenal product carries on tissue oxidation that its marked diminution causes this disease in both adults and infants.

The fundamental function inhibited by vitamine deficiency in scorbutus and infantile scorbutus, therefore, is plainly tissue oxidation.

THE IDENTITY OF THE ANTISCORBUTIC ENZYME IN ANIMALS AND PLANTS.

When recognition of the adrenal secretion as a participant in the respiratory process, both pulmonary and systemic, was urged, much evidence was adduced to the effect that this secretion contained an oxidizing ferment or enzyme which, in 1907 (39), owing to its identity and origin, I termed "adrenoxidase." To convey clearly the farreaching importance of the oxidases (a term introduced by Bertrand, of Paris, in 1896, to identify soluble oxidizing enzymes of organic origin) it may be recalled that tissue cells cannot subsist merely by absorbing oxygen, even when immersed in this gas. The oxygen must, as first held by the Swiss biochemist Schoenbein, in 1857, be ozonized, i. e., activated. The tissues, in other words, need a catalyst, or intermediary between them and the oxygen, whether the latter be free or combined as it is in hemoglobin. Now, adrenoxidase from my viewpoint is the adrenal constituent of oxyhemoglobin which, as we have seen, carries the oxygen from the pulmonary air to the tissues, the latter having a marked affinity for this gas. Owing to the catalytic, i. e., accelerating, powers adrenoxidase has upon the oxygen it carries, the tissues become as it were functionally quickened. It is as such that adrenoxidase becomes the fundamental antiscorbutic vitamine, and that in its absence or diminution, progress towards tissue death occurs.

What do foods contain that corresponds with adrenoxidase?

Among the many oxidases that biochemists have described, either by the name of oxidizing ferments since Planche, a French pharmacist, gave us the guaiacum reaction in 1810, there is one which corresponds in its physiological properties with adrenoxidase; this is tyrosinase, the oxidizing ferment of tyrosin. It is closely related to the alpha-amino acid of hydroxy-phenyl-proprionic acid, thus justifying, in view of its vital importance in deficiency diseases, the term vit-amin introduced by Casimir Funk. Casein, the principal milk protein, contains 4.5 per cent. of tyrosin; but fibroin, the main decomposition product of worm silk, contains as much as ten per cent. It occurs in the intestine during the digestion of protein substances and is found in hemoglobin, according to both Fisher and Abderhalden, in the proportion of 1.5 per cent.

---

[5] The italics are my own.

The kinship between tyrosin, including its oxidizing enzyme tyrosinase, and adrenalin, including also its oxidizing enzyme adrenoxidase, asserts itself in the presence of Howell's (40) statement that while "the rôle the vitamines play in the metabolism of the body is entirely unknown," he also says (41) referring to tyrosin: "This active substance is designated in the literature under a variety of names, those commonly used being epinephrin, adrenalin, and adrenin. It is a basic body which gives a number of characteristic color reactions, and in alkaline solutions is readily oxidized to a substance that fails to exhibit the characteristic epinephrin reaction on heart rate and bloodpressure." The failure of tyrosin, when oxidized, to evoke these phenomena only adds testimony to its identity as adrenalin for the latter likewise fails to cause them when oxidized in vitro. This fact has led many to believe that oxidation renders adrenalin inert in the body whereas in reality it is because it requires the iron which is present in the hemoglobin to enable it to act as catalyst. This metal is also necessary to activate tyrosinase (42). F. M. Durham (43) in fact found that the latter only acted when at least small amounts of iron were present.

In pathology we find additional testimony to this effect. Thus, W. G. MacCallum (44) writes, referring to Addison's disease: "With regard to the pigmentation of the skin, the ideas are vague. Fürth has found that the ferment tyrosinase will produce a black pigment from adrenalin, but it is difficult to understand how, in the absence of the adrenal, such a reaction could aid in the enormous production of pigment seen in Addison's disease." But the difficulty disappears when we take into account, in accord with my views, the large reserve of adrenalin which its identity as a constituent of hemoglobin represents. This may be shown by the observation of Boinet (45) that in seventy-five per cent. of 109 rats from which he had removed both adrenals, hematoidin, i. e., broken down hemoglobin, was found practically everywhere in the tissues, including the lungs.

Zoological biochemistry contributes much to our knowledge of the identity of bronzing. Fifteen years ago (46) a study of this question led me to conclude that this pigmentation was due to an accumulation of the adrenal product and that hematoidin found broadcast was a similar substance. The skin of batrachians, frogs, toads, etc., as is well known, takes part in the respiratory process, and it contains fluids which on exposure to the air become brown then black, precisely as is the case with Addison's disease. Now, Abel (47) "found adrenin in relatively enormous quantity in the skin glands of the toad." Redfield (48) also found a substance similar to it in the metaphores of the horned toad. I had also in 1907 identified both melanin and bronzing as adrenoxidase. Bittorf (49) likewise concluded recently that the bronzing of Addison's disease was due to the formation of an oxidase in the cutaneous epithelium. Again, Hammarsten (50) refers to Gossard as having found tyrosinase in the macerated skin of frogs and toads; he also alludes to this author and to Fürth and Schneider, as being "of the opinion that tyrosin is the mother substance of the melanins." Tyrosin and adrenin are evidently similar bodies, a fact which applies also, therefore, to tyrosinase and adrenoxidase, their oxidizing enzymes.

An additional property common to all oxidizing ferments, including therefore tyrosinase, applies likewise to adrenoxidase, i. e., that of being able to act in infinitesimal quantities as catalyst and as such to activate free oxygen. Schäfer (51) found that fourteen millionths of a gram of the adrenal principle per kilo of animal sufficed to produce maximal effects. In these conditions it might be doubted that this could apply also to respiration; but while Halliburton (52) states that "respiratory pigments, such as hemoglobin, partake of the nature of ferments, for they have a catalytic action," in the evidence submitted concerning the rôle of adrenalin in oxidation, it was shown that doses as small as 1/60 grain of adrenalin increased the respiratory excursions of the lungs that equally small doses raised the basal metabolism rate, the respiratory exchanges, etc.

The temperature factors also emphasize the kinship in point. All investigators place at a relatively low temperature, i. e., between 60° and 70° C., the heat level at which vitamine C is destroyed. In the large number of tests carried out in connection with the food analyses submitted below, I found the limit to be about 67° C. But this applies to the tyrosin, and not to tyrosinase which stands 100° C. and even more. This corresponds with the resistance of adrenoxidase, the oxidizing principle of adrenalin, which as I urged far back in 1903 and 1907, withstands a temperature of 100° C. I. W. Rowe (53) also found in 1915 that ampoules of adrenalin solution stood boiling heat (100° C.) three hours without loss of activity. A third factor is the destructive effect of oxidation, including that produced by the air oxygen, upon foods. Adrenalin, we have seen, is readily oxidized by the air, unless, as I have pointed out, iron in the hemoglobin molecule endow it with catalytic properties. Vitamine C, as has been well illustrated by the labors of Givens and McClugage (54), Hess (55), Dutcher, Harshaw and Hall (56) in their studies of fruits, milk and vegetables, shows all three features.

The kinship between the respiratory rôle of adrenoxidase and that of plant life is further emphasized by considerable testimony including many personal tests, showing that a multitude of plants, other than those used as food, carry on their respiratory process by means of oxidizing enzymes acting with pigments similar in their functional attributes to hemoglobin in animals and hemocyanin in lower forms. Indeed, in the fall the variegated coloring of leaves, and the pink, carmine, red and brown of certain flowers known to contain iron, recall vividly the changes undergone by adrenoxidase, the homologue of tyrosinase, when slowly oxidized through gradual arrest of the capillary circulation. Woods (57) in fact found that "oxidases were responsible for the etiolation of green leaves" (58). Recently, Prof. Bürgi, of Berne (59), urged the therapeutic value of chlorophyll, which though itself deprived of iron, cannot be formed without it. As example, he mentions spinach in which chlorophyll is present in large quantity. As shown in the food analyses submitted below, spinach is rich also in its homologue adrenoxidase, and thus admirably suited as a food for the elaboration of hemoglobin.

VITAMINE C AS A PROMOTER OF TISSUE OXIDATION IN DIETETIC PROPHYLAXIS AND THERAPEUTICS.

In the light of the foregoing data, the antiscorbutic vitamine C acquires far greater importance than has been hitherto accorded it. Scurvy and Barlow's disease, i. e., infantile scurvy, no longer stand from my viewpoint as diseases *per se.* They become, instead, the expression of a morbid process due to inadequate power to take up oxygen from the air owing to deficiency in the blood of the adrenal secretory product—an anadrenia, we might call it—giving rise to a true systemic anoxemia. And it has been observed that such a condition, even in its incipiency, entails a vulnerability to disease.

In the present connection, its dietetic aspect, anadrenia becomes attributable to deficiency of the food constituent tyrosin and its oxidizing enzyme tyrosinase, which as adrenalin and its adrenoxidase, endow the hemoglobin with its power to take up oxygen from the air and carry on tissue oxidation. As such the vitamine C of foods subserves, as far as oxygen is concerned in these processes, the needs of metabolism and prophylaxis. In disease, it also sustains the efficiency of the defensive processes. During convalescence it is essential not only as promoter of tissue oxidation, but also as the fundamental factor of all processes of repair. Vitamine C thus asserts itself as of paramount importance in all functions, normal and morbid, a fact which emphasizes the practical value of knowledge concerning the quantity of this vitamine in the various foods.

Biological tests, i. e., tests in animals, mainly guineapigs in the present connection, have alone been employed so far to determine the antiscorbutic value of foods. The British Medical Research Committee, Funk, Osborne and Mendel, McCollum, and many other investigators have contributed much in this direction.

A very great drawback to food tests in animals, however, is the length of time they take—several weeks as a rule—and the many opportunities for error they afford. Animals of the same species often differ in their resistance to avitaminosis; the stage reached in the scorbutic process may be either beyond or within the limits of possible recovery when the curative vitamine is fed; herbivorous animals may fail to respond favorably to foods suited for carnivorous animals even though they contain the appropriate vitamine; the vitamine content may vary in a given food according to its relative reducing power, its age or freshness; the dryness of the air to which it is exposed, etc.

Chemical tests would remove practically all these difficulties since the food tested, whatever its condition, would stand on its own merits when actually tested; all disturbing features concerned with the animal itself would be avoided, while the time factor would be reduced to a minimum. As long as the chemical nature of the various vitamines was unknown, however, such tests could not, of course, be worked out. With the identity of the antiscorbutic vitamine C interpreted as herein submitted, however, it became possible to do so. An effort in this direction and the difficulties encountered are submitted to facilitate the labors of colleagues in any branch of the medical or dietetic field who may wish to contribute to our knowledge.

THE GUAIAC-H_2O_2 AND THE ADRENALIN-H_2O_2 FOOD TESTS FOR VITAMINE C.

Many disturbing factors had to be taken into account and overcome before satisfactory tests could be devised. Among these may be mentioned the multiplicity of oxidases in plant life, their sensitiveness to oxidation; the variability of various tissues in oxidase content, the degree of acidity of their juices, etc. Citrus fruits, for instance, are so protected by their citric acid that this must be eliminated along with its fluid carrier. Again, Mediterranean lemons will alone react both chemically and biologically. The tomato, although rich in vitamine C, affords an example of the extent to which it may be hidden, for whether fresh or canned, the seeds proved to be its main carriers.

Nor did the guaiac test as practiced ever since it was introduced by Planche in 1810, prove satisfactory in my investigations, mainly because the protection afforded to the tyrosin and tyrosinase by the food tissues varies materially. Covered more or less by other tissue substances, they often failed to influence the reagents. Again, the air was found to part with difficulty with its oxygen in many instances, a doubtful or negative reaction resulting where biological tests had positively shown the presence of vitamine C. A less tenacious oxygen carrier being necessary, hydrogen peroxide proved to be the most satisfactory of the many available. Yet this agent had long been associated by many with organic oxidations. This, however, proved on close analysis to be but a theoretical assumption, even though sustained experimentally, the phenomena being in reality due to the blood adrenoxidase. Indeed, Schoenbein (60) was unable with the most delicate tests to find in the blood even a trace of hydrogen peroxide.

Other technical difficulties encountered were the destructive action of hydrogen peroxide upon the enzymes and the fact that too weak solutions gave but fleeting reactions. After testing many solutions, the most practical was found to be the 1:3000, composed of nine parts of distilled water (thus avoiding contamination with organic matter, calcium, etc.) to one of the three per cent. solution available in shops. This will hereafter be referred to as the H_2O_2-1:3000 solution.

With this solution and fresh tincture of guaiac any food supplied with an oxidase will, with the technic submitted below, give a striking reaction. Yet, guaiac is a promiscuous reagent, being colored blue when enzymes other than tyrosinase are present. A controlling reagent more specific as regards the respiratory process thus became necessary. Adrenalin suggested itself, since in animal blood, our own, it is capable, we have seen, of changing bluish venous blood to red arterial blood. Its value in this connection is readily shown by a striking test within the reach of all. A piece of celery, selecting as white a portion of the stem as possible, is cut into three pieces. On the middle of two of these, an oval area about one half inch is teased and broken up. The three pieces being then set side by side, a few drops of tincture of guaiac are placed into the teased area of one outside piece, and a few drops of the adrenalin 1:1000 solution into that of the other outside piece, thus leaving the middle white piece as control. A few drops of the H_2O_2-1:3000 solution are then poured into both of the oval areas previously stained. In about thirty minutes, the guaiac stained area will have become amethyst blue and the adrenalin area blood red, these colors increasing in intensity for a time.

The need of the tyrosin and its tyrosinase in the food tested to obtain a positive reaction is readily shown by the fact that if either the guaiac or the adrenalin solution is treated alone to the H_2O_2 solution no coloring ensues. If tap water is used, however, there occasionally appears a slight pinkish tinge due to the presence of organic matter containing tyrosinase. Pure tap water, however, when not hard, i. e., free of calcium, may be used for the tests in ordinary circumstances. Again, it must be borne in mind that vitamine C is water soluble. The best results are obtained, therefore, when the food tested is mixed with a little water and thoroughly crushed in the mortar.

As used above for celery the tests are employed as standards for the highest vitamine C value and termed first class in the food lists given below, lower values as to intensity of coloring being graded second, third, fourth, and fifth class respectively. They correspond with the plus signs used by the British Research Committee and other investigators who have conducted tests in animals, the number of plus signs, from four to one, being reduced as vitamine values proved weaker.

Finally, it should be borne in mind that some reactions occur promptly, others slowly. Again, their duration varies; some are lasting but the majority are fleeting, the blue and red disappearing after varying periods and being replaced by a brownish hue corresponding in the variety of its tints with the bronzing of Addison's disease, the browning of certain leaves in the fall, etc.

FOOD VALUES IN VITAMINE C AND EFFECTS OF COOKING.

As determined by these tests, carried out and adjudged as to vitamine value irrespective of any prior reference to the results of biological tests by the British Committee and other observers, the approximate concurrence in the general results—what difference there was being a higher value in some instances shown by the chemical test—illustrated the value of both methods. This applies only to vegetables and fruit, however, so distinctly indicated in scorbutus. In the case of meats, the biological tests carried out in herbivorous animals proved evidently misleading for the chemical tests clearly showed the presence of vitamine C.

VEGETABLES.

First class.—The vegetables which showed this highest rating were cabbage, cauliflower, carrot, tomato, turnip, sweet potato, lima beans, egg plant and the small red radish. Of these the first five which alone had been tested biologically had given four plus and three plus.

Second class.—The second in color intensity were green peas, spinach, beet, corn, both grain and silk; wax beans, string beans, and large peppers. The biological tests of the first five, alone tested, had been three plus, while the string beans had been negative.

Third class.—The weakest, though very distinct in color intensity, among vegetables were the potato, onions (scallions) and squash. Biological tests had given two plus for the potato, which corresponds with the color test, but three plus for onion, the only two tested.

No fourth or fifth class occurred among the raw and fresh vegetables tested, all having shown sufficiently marked reaction to warrant their inclusion in the first three classes.

As to the effects of cooking, boiling apparently destroyed vegetable oxidases of tomatoes, even when their crushed seeds were tested, potatoes (also when fried), corn, squash, wax beans and sweet potato, all three first class vegetables when fresh. "Apparently" is used in this connection because tyrosin is destroyed between 62 and 67° C., according to the density of its cellular container, while its tyrosinase resists 100° C. (the boiling point) some time. Boiling, therefore, by destroying the tyrosin, prevents the reaction, but might not destroy its tyrosinase. As will be shown later, however, destruction of the tyrosin inhibits its adrenalin forming property, in keeping with biological observation. When the cooking was kept below 67° C., vegetables lost only about fifty per cent. of their reactive power in the guaiac-H_2O_2 test, while the adrenalin-H_2O_2 test yielded full value. This test was made with cauliflower which breaks down easily when cooked. Corn lost but twenty-five per cent. in the same conditions. Rapid heating seemed to do less harm to the enzyme than slow heating.

FRUIT.

First class.—Oranges gave a marked but fleeting reaction only, however, when the rind was included. Lemons failed in this class, probably due to the variety on hand and marked acidity. Seedless grapes (pulp) and pineapple gave first class reactions. Biological tests had given orange and lemon four plus, grapes, variety unspecified, one plus; pineapple, untested.

Second class.—This class included pears, peaches, cantaloupe (musk melon) and honey dew melon, all fresh and ripe. Biological tests had given for pears two plus, peaches three plus. Melons untested.

Third class.—Lemon pulp, apples, bananas, plums and cherries constituted this class, the banana making an unexpectedly good showing, close in fact to the higher class. Biological tests had shown for lemons four plus, apples one plus, bananas one plus, plums (fresh prunes) two plus. The higher rating for lemons is said to apply only to the Mediterranean variety (Alice H. Smith). Cherries untested biologically.

SALADS.

First class.—Lettuce, in keeping with the biological tests (four plus) fully merited this class. But celery, untested biologically, also stood high in this category as previously shown.

Second class.—Romaine, cucumber and parsley, all gave positive reactions in this class, though as far as I could find, never tested biologically.

BREAD AND CEREALS.

First class.—Of the foods of this character tested so far, but one seemed to merit this rating; this was cornbread, despite the fact that it had of course been subjected to oven heat, and even though corn itself was only rated second class. The cornbread tested, however, contained as usual both egg and milk.

Cornmeal mush, both boiled and fried, gave no reaction, in keeping with the results of biological tests with cornmeal. Any bread may, however, be made vitamine C active, by adding to it, as in the case of cornbread, agents rich in this vitamine (milk) which stand baking heat.

Third class.—None of the wheat flour breads or cereals in common use that were tested reacted positively. Bran bread with raisins and molasses, often used, also proved negative. But bran bread, graham (bran) crackers which had given negative results biologically, gave a clear third class reaction with the chemical tests, while another kind of bran cracker gave a poor fourth class reaction. Saltines, however, gave a good second class reaction.

MEATS.

In this connection my results, as previously stated, differed totally from those of biological tests which for "lean meat" whether raw or cooked, yielded only one plus, as to vitamine C. This result which had surprised some observers, because it did not correspond with the marked exothermic reactions of muscular tissue, is probably due to the fact that meat was tested in herbivorous animals. With the guaiac-H_2O_2 test alone—omitting the adrenalin feature because the color reaction, red, is too similar to that of the meat and its juices to give reliable reactions—the positive reactions coincided, in the fresh meats used, with the thermo-physical results. The remarkable effects of cooking in this connection must be considered with each meat. Nothing but fresh meat (no imported or Western cold storage meat at least) was used.

First class.—Mutton, both meat and juice, gave very clear first class reactions. Broiling did not impair it in the least, but boiling did so to the extent of sixty-five per cent. Lamb gave a distinctly inferior primary reaction, hardly a third class one, but both broiling and boiling raised it to the first class rate! A mutton or lamb chop when tender and somewhat rare, is essentially rich, therefore, in vitamine C.

Second class.—Beef gave but a second class reaction, though quite distinctly. Boiling, however, reduced it practically to *nil;* thus making boiled beef a negative food as to vitamine C. Roast beef, however, when rare, and its juice, afforded the same surprise as lamb: it gave a clear first class reaction. Broiled beef gave the full second class reaction. Sausages containing beef, frankfürter (hot dog) and bologna, also preserved their second class rating, doubtless because of their skins, which prevented full access of heat and water to their meat. Chicken dark meat gave a full second class reaction, but white meat nothing. Stewed chicken dark meat had lost sixty-five per cent. of its vitamine C activity.

Third class.—Veal gave a good reaction of this class, but dropped to nothing when boiled, a condition to which broiling also reduced it. Roasting, however, repeated the phenomenon observed in the case of beef and lamb, only that it raised the rating to first class!

Fourth class.—Pork fully justified the ostracism to which the Jewish religion has condemned it, at least with respect to its vitamine C content. Not only did it give a poor fourth class reaction, but it showed no improvement when broiled. Boiling, however, did not cause it to lose its reactive power.

FISH AND MOLLUSKS.

First class.—Only oysters and clams gave this reaction among the seafoods tried, no fish giving even the second class. In the third class smelts and perch gave a clear reaction, while the fourth class included halibut and butterfish, and the fifth class, scallops and cod. Shrimps gave no reaction. The adrenalin-H_2O_2 test gave a negative result in the fishes tested, all of which were of the "white blood" series. The red blood series was not tested. As regards biological tests, but two kinds of fish seem to have been tried: salmon and fresh herring, both of which gave a negative result.

As to cooking, the soft tissued butter fish retained its fourth class reactive property when broiled, but boiling annulled all reactive power in every fish tested, also in the lobster, despite the density of the flesh of this crustacean.

DAIRY PRODUCTS.

Fresh summer milk gave a marked first class reaction but only with the guaiac-H_2O_2 reagent, while with adrenalin-H_2O_2 reagent the reaction was but slight, a pale pink being alone obtained. Old but sweet milk, neutral to litmus, i. e., milk kept in the refrigerator just above the freezing point twenty hours, gave but a second class reaction with the guaiac-H_2O_2 reagent, and the same pale pink reaction with the adrenalin-H_2O_2. Biological tests had given two plus for summer milk and plus for winter milk, a rating fifty per cent. lower than the chemical tests have shown. Buttermilk gave a clear third class reaction. As far as I could find it had not been tested biologically.

Cream gave a fourth class reaction but probably due to partial milk content for the addition of fresh skimmed milk increased its reactive power. Restaurant icecream varied according to the kind tested: vanilla icecream gave a first class reaction, but this was doubtless due to the fact that whole milk had been used in its preparation. Chocolate and strawberry icecreams failed to give a reaction. No biological tests were available.

Butter which had responded negatively in the biological tests, gave a clear third class reaction in the chemical tests. Conversely, cheese "made with whole milk" gave biologically one plus, while the chemical tests gave no reaction with either Swiss, roquefort or plain American cheese. This result is probably due to the fact that cream, negative in keeping with fats, is their main constituent. Eggs, both yolk and white, whether fresh or stale, gave negative results both chemically and biologically.

As to cooking, boiling proved fatal to the milk as regards reactive power, when carried out in the open as in households. Eggs, negative normally both biologically and chemically, were not improved, as had been the case with most meats, by frying nor by poaching.

MISCELLANEOUS.

Nuts.—In the reports of biological tests all nuts used commonly as food are recorded as negative. The guaiac-H_2O_2 test gave first class reactions for the hazelnut (filbert) and the pecan; a second class reaction for almonds, and a third class reaction for English walnuts.

Mushrooms.—Three edible kinds were tested. The *clavaria Pistolarius* gave a first class reaction; the *hypholoma perplexum* gave a full second class reaction, while the *puffball lycoperdon* gave a fourth class but distinct reaction. No cooking tests were made.

Soya beans.—These proved surprising as vitamine C carriers, particularly in view of the fact that biological tests had rated them negative. Thanks to the kindness of Prof. Charles F. Hottes, of the University of Illinois, I was able to obtain seven varieties. Of these, the Manchu, Haberlandt, Mongol, Hong Kong, Early Black, and Wilson Black all gave very intense first class reactions, while the Ohio 1913 and Medium Early Yellow gave second class reactions. Their wealth in oil probably interfered with their antiscorbutic action in herbivorous animals, in keeping with results obtained with all other oils in vitamine C biological tests. It is obvious, however, that soya beans, particularly in view of their additional large vitamine B content, are entitled to special researches in dietetic prophylaxis and therapeutics. Heat tests, however, showed that twenty minutes' exposure to the boiling point destroyed their activity. This was preserved entire, however, when the beans were heated ten minutes at 65° C. We have seen that while tyrosinase stands 100° C., tyrosin is destroyed at 67° C.

An all important feature of the effects of heat on foods in general is that the destruction of tyrosin by cooking above 67° impairs its reactive activity in proportion to the protection afforded by its external covering and the rapidity with which it is cooked. Thus, with its hard covering, the soya bean lost but twenty-five per cent. of its reactive power though the heat was raised to 85° in twenty minutes. Had its skin been easily penetrable, ten minutes at 67° would have sufficed to annul its tyrosin value entirely.

All this applies also to other foods; hence the destructive effect of boiling on soft foods, and conversely, the advantage of broiling which embodies a salient advantage: that of being a dry process of cooking. A coating is formed in the external tissues of the food which lays the rôle of the soya bean covering, and protects the deeper tissues. Roasting is similarly protective in its effects; hence the value of roasted meats, which, we have seen, is even raised in the case of lamb and beef to the extent of twenty-five per cent. and in that of veal fifty per cent.

On the whole, the foregoing tests in one hundred and odd foods[6] indicate that cooking in water above 67° C. tends to destroy their tyrosin if the fluid can penetrate the tissues of the food. The vitamine C in these circumstances ceases to become a source of adrenalin, or at least of its precursor, Halle and others (61) having found that the systemic tyrosin was derived from p-oxyphenylethylamin before it became adrenalin. Even if the tyrosinase, which stands a temperature of 100° C., the boiling point, remains undestroyed, scorbutic phenomena result because the tyrosin factor was lacking. This accounts for the fact, shown by biological tests, that foods, autoclaved at high temperatures, caused scorbutus in animals, which were then saved by the same but unheated foods. It explains also the clinical observation that adrenalin and another oxidase, salicylase, were the only helpful agents of the many tried for scurvy during the late war.

The importance of vitamine C in prophylaxis has been referred to, but, of course, other vitamines are necessary to subserve the systemic welfare. Fortunately, the foods studied in the foregoing list practically all contain more or less of vitamines A and B, enough, at least, to protect the ubiquitous fanatic who, to avoid disease, will wish to limit his diet to vitamine C. Again, as I have pointed out elsewhere, it is probable that besides the adrenal homologue tyrosin (tyrosinuria, etc.), various bodies excreted, bilirubin, biliverdin, urobilin, etc., include at least adrenal products, and that the body appropriates from foods no more than its actual needs. What the body cannot do, however, is to compensate for deficient intake of vitamine C and if its rôle in tissue oxidation is taken into account, the list of diseases which its absence or deficiency favors directly or indirectly is, even on cursory analysis, an extensive one indeed.

In disease *per se,* it would seem as if the very life of the patient would depend, particularly in the acute infections of an adynamic type, upon his ability to muster his defensive resources. What adequate tissue oxidation means in this process is self evident. Vitamine C foods thus become potent adjuncts to pharmacological measures. Here again, however, a word of caution is necessary. As I have urged elsewhere (62) hemolysis and autolysis are directly influenced by certain ductless glands early in various infections, pulmonary, cardiac, vascular, intestinal, cerebrospinal, etc., excessive oxidation (hyperthermia) being an active factor in the process. That a diet rich in vitamine C would activate this morbid process is therefore likely. It would seem, therefore, that great circumspection is as necessary in the dietetics of the sick as it is in the use of remedies. This, in turn, suggests that knowledge of the chemical nature of the vitamines will enable us to increase the efficiency of our humanitarian efforts.

A Diagnostic Criterion and Serum Therapy in Lethargic Encephalitis*

By M. NEUSTAEDTER, M.D., Ph.D.,
New York.

A great deal of literature on the diagnosis of lethargic encephalitis, socalled, has been published by clinicians in this country and abroad since 1917, when Von Economo described as lethargic encephalitis and Netter as *encephalite lethargique epidemique* the epidemic disease with symptoms referable mainly to lesions in the midbrain. It was since then observed that the entire neuraxis might be involved or the peripheral nerves only.

To summarize the reports of all observers we found that the prodromal stage varied in different epidemics and in different individuals. Thus it might have been ushered in with headache, meningismus, ophthalmoplegia and slight fever. Again somnolence and diplopia were a marked feature and in some regions inflammations of the respiratory tract, nausea and vomiting were superimposed on the above mentioned syndromes. Some observers reported cases beginning with radicular pains, or a Parkinson syndrome and no temperature. In several cases of my series choreiform movements or myoclonus with radicular pains were the initial symptoms. In most of the cases headache was a prominent symptom.

In the same way the subsequent clinical picture is so diverse that our difficulty in making a positive diagnosis is still more enhanced. The most common syndrome is that referable to a lesion in the midbrain. Here somnolence is the rule. Most commonly the motor cranial nuclei are involved. Thus we see ocular ptosis, partial or complete ophthalmoplegia, with strabismus or diplopia as the case may be, anisocoria and irregularity of the pupils, facial paralysis of the peripheral type and also disturbance of the intercalating neurons in the superior caliculi giving rise to a partial or complete Argyll Robertson pupil. Hemipareses and even hemiplegias with aphasia have been seen quite frequently. In one instance I have seen hemiatrophy of the tongue with paralysis of the same side. Optic neuritis and even papilledema have been reported. Impairment of the vestibular and cerebellar pathways were followed by ataxia and nystagmus. At times the basal ganglia became involved and with the Parkinsonian features, chorea, chorioathetosis or dystonia as a result. Some have reported spinal types with symptoms of transverse myelitis, syringomyelia and also those referable to anterior horn lesions. Then, again, neuritides with herpetic eruptions were the only symptoms. Various endocrine disturbances or even psychoses are reported as concomitants of the affection. The temperature range was between apyrexia and 106° F.

The blood picture, according to various reports, showed a white cell count varying between three thousand and twenty-five thousand. The spinal fluid was always clear and under slightly increased or normal pressure, its cell count ranging between two and five hundred. They were of the small mononuclear type exclusively or markedly predominating. The Wassermann reaction was negative, unless lues was present and the Lange test showed a curve elevation beginning on the left side and receding to the right in the majority of the cases, in some normal. The curve, if any, was typically meningitic.

It may be of interest to note the relative frequency of these signs and symptoms in the series of 103 cases seen in my private and hospital practice within the last two and a half years. There were sixty-four males and thirty-nine females; their ages ranged between two years and seventy-six years; temperature from 99° to 106° F. Headache was the most prominent symptom in ninety-three of the cases; vomiting twelve; hyperidrosis, twenty-one; lethargy, thirty-two; somnolence, twenty-nine; insomnia, twenty-two; vertigo, twenty-five; root pains, twenty; incontinence of urine and feces, six; herpes, two; blurred vision, twenty-eight; diplopia, twenty-two; ptosis, twenty-three; anisocoria, twenty-two; paralysis of the abducens, eleven, the facial ten, and the hypoglossal, three; dyspnea, six; hiccough, two; myoclonus, twenty-two; nystagmus, twelve; trifacial pains, three; hemiparesis or hemiplegia, thirty; aphasia, eight; chorea, five; Parkinson, eleven; hemihypesthesia, four; papilledema, nine; optic neuritis, four; epileptiform convulsions, four. Pathological reflexes: absence of abdominals, forty-six; ankle clonus, thirty-one; toe extension phenomenon, twenty-five; Argyll Robertson pupils, thirty-eight; irregular pupils with sluggish light reflex, forty; Kernig, forty-nine; rigidity of neck, fifty-one; psychoses, twenty-nine. The Wassermann reaction was positive (++++) in three cases.

It certainly becomes evident from the facts given above that neither the clinical picture nor the cytology, chemistry and serology of the blood and spinal fluid, so far as reported, gives any definite clue that may be looked upon as a criterion for diagnosis. In epidemics the acute cases with somnolence and the classical symptoms referable to lesions in the midbrain present no difficulty, but how about the mild ones and those without the classical symptoms? How about the socalled abortive types or those occurring sporadically? How about those with a positive Wassermann? What about these with papilledema that may justifiably be diagnosed as a brain neoplasm or abscess, especially with a blood count of twenty-five thousand white cells? Then, again, how about the spinal and peripheral nerve types? In all these syndromes we have no positive means of etiological differentiation, for they appear in consonance with the site of the lesion and not the particular etiological factor. So that without any specific criterion it is guess work at best.

Early in the epidemic many observers thought that the affection was a cerebral type of epidemic poliomyelitis. The majority of them, however, are now of the opinion that it is an entirely new entity.

---

*Read before the Yorkville Medical Society, October 16, 1922, and the German Medical Society, November 6, 1922.

It must be borne in mind that the gross and histopathological picture of the disease is the same in both. Clinically there were reported cerebral, cerebellar, pontile, bulbar and meningitic types of epidemic poliomyelitis. Radicular pains were fairly universal in late poliomyelitis epidemics. Fraenkel-Hochwart called my attention to it in Washington at the Congress of Demology, stating that in former years no radicular pains were recorded in poliomyelitis. The blood and spinal fluid findings are analogous in both diseases, with the possible exception that in poliomyelitis a higher cell count in the spinal fluid was reported in some cases. The temperature range is the same in both. The etiological agent seems to have the same morphology, staining and cultural characteristics and resists and is destroyed by the same agents as that of poliomyelitis, if we are to accept Flexner and Nogouchi's findings in poliomyelitis and Strauss and Loewy's in epidemic encephalitis. The mortality rate seems to be about the same in both. The age and time incidence is decidedly different in the two. Poliomyelitis has a predilection for infants and children and epidemics occur usually in the summer and fall, while encephalitis attacks mainly adults and the epidemics are limited to the winter and spring. Paralyses in poliomyelitis appear with the fall in temperature, in encephalitis with the rise. Experimentally we find it difficult to transmit the virus of encephalitis to monkeys, while comparatively easy to rabbits. Poliomyelitis virus, on the other hand, is readily transmitted to monkeys and not at all to rabbits.

The similarities of both diseases remind us of the different variations of the same species of germs in given infections, as the pneumococcus and paratyphoid groups. It is indeed interesting to remember that the virus of syphilis, for instance, produces different clinical entities and even different pathological lesions, so that the possibility of variations in the species of Treponema pallidum is strongly suspected by many.

The similarities of poliomyelitis and epidemic encephalitis, baffling as they are, I have attempted to investigate experimentally. In 1919 in collaboration with Dr. Larkin and Dr. Banzhaf (1) we succeeded in establishing that the poliomyelitis virus was completely neutralized *in vitro* by the serums of patients convalescent from lethargic encephalitis and the mixture, when injected intracerebrally into monkeys, completely protected six animals from poliomyelitis. That serum of patients convalescent from poliomyelitis completely neutralizes poliomyelitis virus *in vitro* and protects monkeys against the disease has been established by Landsteiner, Flexner and Lewis, Netter and Levaditi, Roemer, Anderson and Frost, and others.

Encouraged by these results we were led to attempt a complement fixation with poliomyelitis antigen in spinal fluids of patients acutely ill with encephalitis, since in 1916 (2) we had had good results with complement fixation tests in spinal fluids of patients acutely ill with poliomyelitis, with this specific antigen. In collaboration with Dr. Hala and Dr. Banzhaf sixty spinal fluids of patients suffering from frank or suspected encephalitis lethargica were tested with poliomyelitis antigen for complement fixation. There were forty-three positives; of these sixteen were ++++, six were +++, eleven were ++, ten +, and three +; fourteen were negative. Of the latter three gave a positive Wassermann reaction, one turned out to be a traumatic meningeal hemorrhage, two spinal cord tumors, and three syringomyelia. I shall not dwell extensively on this point, since it is to be the subject of a special paper, but will indicate here that we may assume to have a valuable aid in the diagnosis of lethargic encephalitis in the complement fixation with this specific antigen; if indeed not a criterion.

It would logically follow from the positive results of these two phases of experiment that, since there is no specific therapeutic agent for the disease, the antipoliomyelitis horse serum prepared by me in collaboration with Dr. E. Banzhaf (3) at the Research Laboratories of the Department of Health, New York City, since 1916, might be of value in its treatment.

For this purpose we selected six cases in the neurological service of Kings County Hospital, thirteen cases in the service of Dr. Schwertfeger of the Lenox Hill Hospital, and five private cases. Only severe cases were treated. Mild cases or such as showed no alarming symptoms were given the usual palliative measures. Early in the treatment the serum was injected intraspinally, but we abandoned this method since we had a few severe reactions. Intravenously the results were more reassuring and there was hardly ever a reaction. Twenty to thirty c. c. were injected in twenty-four hour intervals and in one case, a very severe one, two injections were given in twelve hour intervals. Eighteen patients recovered completely without any sequelæ, one with a mild psychosis, and six died.

In order to judge the merits of the serum therapy I may describe four cases illustrative of my point of view and the series.

CASE I.—A. K., male, thirty-two years of age. Admitted to Lenox Hill Hospital on April 2, 1922, in the service of Dr. Schwertfeger. He was somnolent and vertiginous and his temperature was 99° to 99.8°. His neurological status was reported as follows: Nystagmus, ptosis of left eyelid, anisocoria, pupils sluggish to light, prompt to accommodation, left abdominal myoclonus and later radicular pains. He was losing weight rapidly. Superficial and deep reflexes were present. He was doing fairly well during two months following with expectant treatment although the spinal fluid poliomyelitis fixation was ++++. Early in June he became lethargic, his temperature rose to 103° and his general condition became alarming. His spinal fluid showed a cell increase, lymphocytes exclusively, globulin +, poliomyelitis fixation ++++. Antipoliomyelitis serum therapy was decided upon. He was given six intravenous injections of twenty c. c. doses in twenty-four hour intervals. The fever in the meantime was rising to 106°. After the third injection the fever receded only to rise again. After the sixth the temperature dropped to normal, the patient continued to improve and made a full recovery without any sequelæ. He left the hospital a week after the last injection and the only complaint he made to me was that he had a ravenous appetite.

CASES II and III.—Two girls, aged sixteen and eighteen years, respectively. One was admitted to the Kings County Hospital and the other to the Lenox Hill Hospital with choreiform movements of practically all the muscles of the body. The patient in Kings County Hospital was treated for seven weeks in the usual manner without any improvement. Her temperature was 99° to 100°. Intraspinous injection of her own serum according to the Goodman method had no effect. Her spinal fluid poliomyelitis fixation was ++. Five intravenous injections of the antipoliomyelitis serum were administered in twenty-four hour intervals. After the second injection marked improvement set in and after the fifth no tremor was noticeable. A week after the last injection she was discharged cured.

The patient in the Lenox Hill Hospital was observed for a month and received the autoserum treatment without any effect. Her spinal fluid was ++ positive with poliomyelitis antigen, her temperature normal. Three intravenous injections of the antipoliomyelitis serum were given with good effect and one week after the last injection she was discharged as cured.

Case IV.—M. F., male, aged fifty-six years. This patient was seen by me at his residence with Dr. Wynn on May 6, 1922, when he complained of general asthenia, insomnia, restlessness and headache. Neurological status: pupils irregular and sluggish to light, prompt to accommodation, fundi oculi negative. Reflexes: abdominals absent, cremasterics present, patellars brisk, achilles present, plantar flexion on right side, extension toe on left side, slight clonus on both sides, slight Kernig and neck rigid. Temperature 103°. Spinal fluid, not under pressure, no increase in cells, globulin +, fixation with poliomyelitis antigen +++. Within the next two days the fever rose to 106° and the patient became rather somnolent and began to hiccough. His pupils were now fixed to light, a complete Argyll Robertson pupil. He received five intravenous injections of antipoliomyelitis serum, two in twelve hour intervals and the rest in twenty-four hour intervals. The temperature dropped to normal after the first two injections, then rose again and after the fifth went to normal and continuel normal. Two weeks after the last injection the patient, fully recovered, went to Europe on a pleasure trip. He was seen in Vienna by Von Economo, who pronounced him completely cured.

The Wassermann reaction of all treated cases was negative and the Lange test showed the curve described above.

CONCLUSIONS.

1. Positive complement fixation of spinal fluids with poliomyelitis antigen seems to be a diagnostic criterion in epidemic encephalitis lethargica.

2. Antipoliomyelitis horse serum seems to be of value in the treatment of this disease in the absence of any other specific agent.

I desire to extend my thanks to Dr. William W. Hala and Mr. Janke of the Kings County Hospital and to Dr. Schwertfeger, Dr. Blumgarten, Dr. Garbath, and Dr. Cramer of the Lenox Hill Hospital for their kind encouragement and assistance.

Educational Methods of the Various Schools of Medicine and the Treatment of Disease*

By JAMES M. ANDERS, M.D., LL.D.,
Philadelphia.

The political philosopher rightly assumes that good government remains the greatest of human blessings. Aristotle observes that all settled states embody an aspiration to live well. That the progress and well being of a nation depends largely upon the character of its medical service and its sanitary status or health rate is now generally appreciated. It is, therefore, gratifying to note that at no previous stage of human history has the medical profession played such a leading rôle in the affairs of community and state as at the present day.

In America the modern physician has become a more useful social being than at any point in the nation's history. In a democracy like ours, however, the danger that the pendulum, which is never at rest, may swing too far in the direction of socializing medicine, is obvious.

Analysis of the past half century with all its marvelous advances in the medical and cognate sciences, shows that the record of the profession of America for this period is in certain particulars more or less pathetic. It would appear to bear some, at least, of the seeds of its own undoing, as will appear obvious hereafter. Progressive members of our profession naturally welcome the trend of recent medicine toward greater participation in practical community affairs and the correlation of the modern humanities; they likewise warmly welcome the material elevation of educational standards in our medical schools. On the other hand the modern program still presents defects, both from the viewpoint of medical education and of the public needs in relation to the character of medical service rendered.

The literature on the problems of medical education is extensive and the testimony, as would be expected, is not all in one direction. On account of the leading importance of the subject, one may be pardoned for participating in its discussion with the hope of helping to decide policy and crystallize public opinion. Fortunately, as already stated, cooperation between the medical profession and the public is growing steadily closer, chiefly through the efforts of professional organizations, local and federal health agencies and civic associations. Movements for the education of the public in hygienic living have been and are in progress, but there have not been formulated and put into operation proper plans for the purpose of enlightening the people in the fuller and saner use of medical art and science in the treatment of disease.
